CONTENTS

JANUARY

EDITORIAL: Remembrance of times past: the significance of c-*fos* in pain 1
R. Munglani, B. G. Fleming and S. P. Hunt

CLINICAL INVESTIGATIONS

Dobutamine increases oxygen consumption during constant flow cardiopulmonary bypass 5
W. Karzai, A. Lötte, M. Günnicker, U. M. Vorgrimler-Karzai and H.-J. Priebe

Effects of sevoflurane and isoflurane on systemic vascular resistance: use of cardiopulmonary bypass as a study model 9
G. Rödig, C. Keyl, G. Wiesner, A. Philipp and J. Hobbhahn

Cardiopulmonary bypass with modified fluid gelatin and heparin-coated circuits 13
P. G. M. Jansen, H. te Velthuis, W. R. Wildevuur, M. A. J. M. Huybregts, E. R. Bulder, H. I. van der Spoel, A. Sturk, L. Eijsman and C. R. H. Wildevuur

Pupil changes during cardiopulmonary bypass 20
G. C. Fletcher, A. J. Asbury and J. H. Brown

Vecuronium infusion requirements in paediatric patients in intensive care units: the use of acceleromyography. 23
U. M. Hodges

Pharmacokinetics of rocuronium after bolus and continuous infusion during halothane anaesthesia..... 29
E. P. McCoy, R. K. Mirakhur, V. R. Maddineni, J. M. K. H. Wierda and J. H. Proost

Effect of suxamethonium on the auditory evoked response in humans 34
M. D. Brunner, D. Nathwani, P. A. Rich, C. Thornton, C. J. Doré and D. E. F. Newton

Analgesic effect in humans of subanaesthetic isoflurane concentrations evaluated by evoked potentials......... 38
D. Roth, S. Petersen-Felix, P. Bak, L. Arendt-Nielsen, M. Fischer, P. Bjerring and A. M. Zbinden

Use of near infrared spectroscopy to estimate cerebral blood flow in conscious and anaesthetized adult subjects 43
H. Owen-Reece, C. E. Elwell, W. Harkness, J. Goldstone, D. T. Delpy, J. S. Wyatt and M. Smith

Effect of transdermal hyoscine on nausea and vomiting during and after middle ear surgery under local anaesthesia.. 49
P. Honkavaara

Single dose i.v. tropisetron in the prevention of postoperative nausea and vomiting after gynaecological surgery 54
V. Capouet, C. De Pauw, B. Vernet, D. Ivens, V. Derijcke, L. Versichelen, H. van Aken, B. Ickx, L. Ritter and F. Hulstaert

Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section 61
D. G. Thomas, S. C. Robson, N. Redfern, D. Hughes and R. J. Boys

A double-blind comparison of 0.25% ropivacaine and 0.25% bupivacaine for extradural analgesia in labour. 66
J. M. Eddleston, J. J. Holland, R. P. Griffin, A. Corbett, E. L. Horsman and F. Reynolds

Absence of an early pre-emptive effect after thoracic extra-dural bupivacaine in thoracic surgery 72
J. L. Aguilar, R. Rincón, V. Domingo, P. Espachs, M. J. Preciado and F. Vidal

Prilocaine 3% is superior to a mixture of bupivacaine and lignocaine for peribulbar anaesthesia 77
U. R. Döpfmer, D. G. Maloney, P. A. Gaynor, R. M. H. Ratcliffe and S. Döpfmer

Haemodynamic effects of moderate normovolaemic haemodilution in conscious and anaesthetized patients 81
P. Biboulet, X. Capdevila, D. Benetreau, P. Aubas, F. d'Athis and J. du Cailar

Analysis of ethanol in expired air during low-flow isoflurane anaesthesia 85
J. Olsson and R. G. Hahn

Perioperative mucosal pH and splanchnic endotoxin concentration in orthotopic liver transplantation 90
M. Welte, B. Pichler, J. Groh, M. Anthuber, K.-W. Jauch, E. Pratschke, F.-P. Lenhart, M. Haller, L. Frey and K. Peter

LABORATORY INVESTIGATIONS

Nitrous oxide or halothane, or both, fail to suppress c-*fos* expression in rat spinal cord dorsal horn neurones after subcutaneous formalin.................................. 99
W. Z. Sun, B. C. Shyu and J. Y. Shieh

Effects of morphine on atrial preparations obtained from non-failing and failing human hearts.................. 106
F. Llobel and M. L. Laorden

A perfusion system for *in vitro* measurement of human cilia beat frequency.................................... 111
D. A. Selwyn, A. Gyi, J. H. Raphael, A. Key and J. A. Langton

Effects of 3 MAC of halothane, enflurane and isoflurane on cilia beat frequency of human nasal epithelium *in vitro* 116
J. H. Raphael, D. A. Selwyn, S. D. Mottram, J. A. Langton and C. O'Callaghan

Effect of phosphodiesterase inhibitors on human arteries *in vitro* 122
M. B. Vroom, M. Pfaffendorf, H. B. van Wezel and P. A. van Zwieten

Effect of pneumoperitoneum and Trendelenburg position on gastro-oesophageal reflux and lower oesophageal sphincter pressure 130
J. P. Tournadre, D. Chassard, K. R. Berrada and P. Bouletreau

REVIEW ARTICLE

Recent developments in the pathophysiology and management of pre-eclampsia 133
M. C. Mushambi, A. W. Halligan and K. Williamson

SHORT COMMUNICATIONS

Extradural and subarachnoid catheterization using the Seldinger technique.................................... 149
E. M. Delhaas

Regional anaesthesia for outpatient nasal surgery.......... 151
S. Molliex, M. Navez, D. Baylot, J. M. Prades, Z. Elkhoury and C. Auboyer

Effect of smoking on dose requirements for vecuronium.. 154
H. Teiriä, P. Rautoma and A. Yli-Hankala

CASE REPORTS

Airway problems in carotid endarterectomy............. 156
F. J. Munro, A. P. Makin and J. Reid

Mivacurium chloride and late onset congenital myopathy. 160
M. Parmar and R. P. F. Scott

Anaesthesia and juvenile hyaline fibromatosis 163
B. Norman, N. Soni and N. Madden

CORRESPONDENCE

Visceral pain during Caesarean section............................. 167
Cannabis as a medicine... 167
Naproxen after day-case laparoscopic sterilization.......... 168
Systolic pressure variation—a way to recognize dynamic hyperinflation 168
Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia 169
RAE tube obstruction during tonsil dissection............... 170
Extradural clonidine for postoperative pain relief........... 171
Porphyria, propofol and rats.. 171

BOOK REVIEWS

Baillières Clinical Anaesthesiology: New Pharmacological Vistas 173
Basics of Transoesophageal Echocardiography 173
Modulation of the Inflammatory Response in Severe Sepsis 173
Sedation and Analgesia in the Critically Ill 174
Anaesthesia: Review 11 174
A Practical Approach to Cardiac Anesthesia 174

Erratum 175

FEBRUARY

EDITORIAL: Prospects for management of peripheral vascular failure in septic shock 177
J. D. Allen and N. A. Herity

CLINICAL INVESTIGATIONS

Effect of age on MAC in humans: a meta-analysis 179
W. W. Mapleson

Omitting nitrous oxide in general anaesthesia: meta-analysis of intraoperative awareness and postoperative emesis in randomized controlled trials 186
M. Tramèr, A. Moore and H. McQuay

Cognitive failures after general anaesthesia for day-case surgery 194
Y. Tzabar, A. J. Asbury and K. Millar

Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery 198
M. Raucoules-Aimé, Y. Labib, J. Levraut, P. Gastaud, C. Dolisi and D. Grimaud

Pulmonary uptake of sufentanil during and after constant rate infusion 203
F. Boer, E. Olofsen, J. G. Bovill, A. G. L. Burm, A. Hak, M. Geerts and K. E. Wetselaar

Does pre-incisional thoracic extradural block combined with diclofenac reduce postoperative pain after abdominal hysterectomy? 209
A. Espinet, D. J. Henderson, K. A. Faccenda and L. M. M. Morrison

Influence of oral clonidine on the ventilatory response to acute and sustained isocapnic hypoxia in human males. 214
I. T. Foo, P. M. Warren and G. B. Drummond

Comparison of nicardipine, diltiazem and verapamil for con-trolling the cardiovascular responses to tracheal intubation 221
K. Mikawa, K. Nishina, N. Maekawa and H. Obara

Preoperative infusion of amino acids prevents postoperative hypothermia 227
E. Selldén, R. Brånström and T. Brundin

Time course of potentiation of mivacurium by halothane and isoflurane in children 235
O. A. Meretoja, K. Wirtavuori, T. Taivainen and K. T. Olkkola

Edrophonium antagonism of intense mivacurium-induced neuromuscular block in children 239
M. Abdulatif, A. Al-Ghamdi, M. Al-Sanabary and M. E. Abdel-Gaffar

Fuzzy logic control of inspired isoflurane and oxygen concentrations using minimal flow anaesthesia 245
M. Curatolo, M. Derighetti, S. Petersen-Felix, P. Feigenwinter, M. Fischer and A. M. Zbinden

LABORATORY INVESTIGATIONS

Methylprednisolone inhibits endotoxin-induced depression of contractile function in human arteries *in vitro* 251
I. Tsuneyoshi, Y. Kanmura and N. Yoshimura

Central nuclei and spinal pathways in feedback inhibitory spinal cord potentials in ketamine-anaesthetized rats 258
S. Denda, K. Shimoji, M. Tomita, H. Baba, T. Yamakura, H. Masaki, H. Endoh and S. Fukuda

Relaxant effect of ketamine and its isomers on histamine-induced contraction of tracheal smooth muscle 266
K. Hirota, T. Sato, S. F. Rabito, E. K. Zsigmond and A. Matsuki

Interaction of i.v. anaesthetic agents with 5-HT_3 receptors 271
B. L. Appadu and D. G. Lambert

Effects of morphine on human nasal cilia beat frequency *in vitro* 274
D. A. Selwyn, J. H. Raphael, D. G. Lambert and J. A. Langton

Electromyographic and mechanomyographic characteristics of neuromuscular block by magnesium sulphate in the pig 278
C. Lee, X. Zhang and W.-F. Kwan

A model to describe the rate of oxyhaemoglobin desaturation during apnoea 284
A. D. Farmery and P. G. Roe

Nitrous oxide and the rate of gas uptake from an unventilated lung in dogs 292
C. J. Joyce, A. B. Baker, R. Parkinson and M. Zacharias

Interpleural local anaesthesia: anatomical basis for mechanism of action 297
A. G. McKenzie and S. Mathe

REVIEW ARTICLE

Ropivacaine 300
J. H. McClure

SHORT COMMUNICATIONS

Dose of propofol for laryngeal mask airway insertion in children: effect of premedication with midazolam 308
R. A. Martlew, G. Meakin, R. Wadsworth, A. Sharples and R. D. Baker

Comparison of i.v. and s.c. diamorphine infusions for the treatment of acute pain in children 310
D. Semple, L. A. Aldridge and E. Doyle

Prospective evaluation of pharmacokinetic model-controlled infusion of propofol in adult patients 313
T. G. Short, T. A. Lim and Y. H. Tam

Effect of ondansetron on nausea and vomiting after middle ear surgery during general anaesthesia 316
P. Honkavaara

Extradural analgesia with clonidine and fentanyl compared with 0.25% bupivacaine in the first stage of labour 319
D. J. Buggy and C. MacDowell

CASE REPORTS

Sudden onset of subarachnoid block after subdural catheterization: a case of arachnoid rupture? 322
D. W. Elliott, F. Voyvodic and P. Brownridge

Elective forceps delivery and extradural anaesthesia in a primigravida with portal hypertension and oesophageal varices 325
J. A. Heriot, C. M. Steven and R. S. Sattin

Bilateral severe pain at L3–4 after spinal anaesthesia with hyperbaric 5% lignocaine 328
R. Rodríguez-Chinchilla, A. Rodríguez-Pont, T. Pintanel and F. Vidal-López

Pulsed saline lavage causing venous air embolism in a patient with Paget's disease 330
C. A. Sides

CORRESPONDENCE

Inadvertent infusion of glucose saline into the extradural space 332
Cardiac arrest at induction of anaesthesia for Caesarean section 332
Day-case cataract surgery 333
Effects of propofol on rabbit mesenteric arteries and veins 333
A pitfall in the use of the Altman nomogram for power estimation 334
Change in neostigmine ampoules 334
Volume preloading, spinal anaesthesia and Caesarean section 334
Accidental insertion of an extradural catheter 336
Transoesophageal echocardiography in chest trauma 336

BOOK REVIEWS

Anaesthesia and Critical Care Manual, 2nd Edn 338
Anaesthesia and Intensive Care for Patients with Liver Disease 338
Principles and Practice Series: Respiratory Support 338
The ABC of Resuscitation, 3rd Edn 338

Erratum 339

MARCH

EDITORIALS:

I: Remifentanil—an opioid for the 21st century 341
J. P. Thompson and D. J. Rowbotham
II: Voltage-sensitive Ca^{2+} channels and anaesthesia 344
K. Hirota and D. G. Lambert

CLINICAL INVESTIGATIONS

Prediction of postoperative nausea and vomiting using a logistic regression model 347
C. C. Toner, C. J. Broomhead, I. H. Littlejohn, G. S. Samra, J. G. Powney, M. G. A. Palazzo, S. J. W. Evans and L. Strunin
Metabolic and hormonal responses to induced hypotension for middle ear surgery 352
M. C. Newton, G. D. Chadd, B. O'Donoghue, S. M. Sapsed-Byrne and G. M. Hall
Influence of dose and timing of administration of morphine on postoperative pain and analgesic requirements 358
M. D. Mansfield, K. S. James and J. Kinsella
Recovery after desflurane anaesthesia in the infant: comparison with isoflurane 362
A. R. Wolf, R. A. Lawson, C. M. Dryden and F. W. Davies
Perioperative changes in α_1-acid glycoprotein concentrations in infants undergoing major surgery 365
P. D. Booker, C. Taylor and G. Saba
Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone 369
H. J. Spens, G. B. Drummond and P. K. Wraith
Slow ventilatory dynamics after isocapnic hypoxia and voluntary hyperventilation in humans: effects of isoflurane 374
A. Dahan, J. van Kleef, M. van den Elsen, R. Valk and A. Berkenbosch
Comparison of the pharmacodynamics and pharmacokinetics of an infusion of *cis*-atracurium (51W89) or atracurium in critically ill patients undergoing mechanical ventilation in an intensive therapy unit ... 382
A. H. Boyd, N. B. Eastwood, C. J. R. Parker and J. M. Hunter
Effect of isoflurane and sevoflurane on the magnitude and time course of neuromuscular block produced by vecuronium, pancuronium and atracurium 389
L. E. H. Vanlinthout, L. H. D. J. Booij, J. van Egmond and E. N. Robertson
Performance assessment of a fuzzy controller for atracurium-induced neuromuscular block 396
D. G. Mason, N. D. Edwards, D. A. Linkens and C. S. Reilly
Comparison of arterialized venous with arterial blood propofol concentrations during sub-anaesthetic infusions in volunteers 401
K. R. Johnston, M. D. Vickers and W. W. Mapleson
Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement 405
B. M. Weiss, D. R. Spahn, H. Rahmig, R. Rohling and T. Pasch
Haemodilution induces a hypercoagulable state 412
T. G. Ruttmann, M. F. M. James and J. F. Viljoen
Effect of tramadol on depth of anaesthesia 415
J. F. Coetzee, J. S. Maritz and J. C. du Toit

LABORATORY INVESTIGATIONS

Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function 419
S. Dalmas, S. C. U. Marsch, D. M. Philbin, D. J. Gavaghan, W. A. Ryder and P. Foëx
Effects of carbon dioxide embolism with nitrous oxide in the inspired gas in piglets 428
J.-B. Nyarwaya, S. Pierre, J.-X. Mazoit, V. Umbrain, M. Romain, K. Samii and A. d'Hollander

REVIEW ARTICLE

Sevoflurane—a long-awaited volatile anaesthetic 435
I. Smith, M. Nathanson and P. F. White

SHORT COMMUNICATIONS

Effect of neuromuscular block on depth of anaesthesia as measured by the auditory evoked response 446
C. E. Richmond, A. Matson, C. Thornton, C. J. Doré and D. E. F. Newton
Comparison of ondansetron and prochlorperazine for the prevention of nausea and vomiting after adenotonsillectomy 449
A. A. van den Berg
Smaller children have greater bupivacaine plasma concentrations after ilioinguinal block 452
T. Smith, P. Moratin and H. Wulf
Laryngeal mask airway performance: effect of cuff deflation during anaesthesia 456
G. N. Morris and R. Marjot
Delayed forced air warming prevents hypothermia during abdominal aortic surgery 459
J. Karayan, D. Thomas, L. Lacoste, K. Dhoste, J. B. Ricco and J. Fusciardi
Fentanyl increases intracelluar Ca^{2+} concentrations in SH-SY5Y cells 461
A. L. Wandless, D. Smart and D. G. Lambert

CASE REPORTS

Myocardial ischaemia associated with Ehlers-Danlos syndrome 464
C. M. Price, S. Ford, L. St John Jones and V. Murday
Reducing the potential morbidity of an unintentional spinal anaesthetic by aspirating cerebrospinal fluid.... 467
P. Southorn, G. M. S. Vasdev, R. C. Chantigian and G. M. Lawson

COMMENTARY

Consensus statement on autologous transfusion 470

CORRESPONDENCE

Histamine release by neuromuscular blocking agents.... 471

EDITORIAL

Remembrance of times past: the significance of c-*fos* in pain

"Everlasting layers of ideas, images, feelings have fallen upon your brain..., Each succession has seemed to bury all that went before. And yet in reality not one has been extinguished..."

Thomas de Quincey

Advances in neurobiology have provided us with the tools to identify the molecular events that underlie functional and structural change within the nervous system. Examining the molecular responses to nerve stimulation and injury have led not only to an increased understanding of the biological basis of acute and chronic pain states, but also suggest a molecular memory for painful stimulation. One particular molecular marker, c-*fos*, has been the focus of much research after the key observation that painful, but not innocuous, peripheral stimulation rapidly causes the expression of c-*fos* gene expressions within the spinal cord [1]. The article by Sun, Shyu and Shieh [2] in this issue of the journal demonstrates that apparently adequate anaesthesia fails to prevent expression of an immediate early gene "c-*fos*" within the spinal cord after painful peripheral stimulation. In this editorial, clinical consequences of this observation are discussed in relation to the fundamental role of c-*fos* in linking short-term stimuli to long-term structural change within the nervous system.

Immediate early genes such as v-*fos* (viral-*fos*) were first shown to be capable of inducing cell proliferation and were subsequently known as proto-oncogenes. When the same gene was then described in cells it was termed c-*fos* (cellular-*fos*). More than 100 immediate early genes are now known and have fundamental roles in cell proliferation, differentiation and programmed cell death [3]. The basic property shared by all is that they are capable of being induced (i.e. their messenger RNA is produced) without prior protein synthesis, typically within minutes after stimulation. This observation indicates that the cellular machinery required to effect gene transcription is in a state of readiness and contrasts with the "late response genes" which do require further *de novo* protein synthesis before their transcription can be altered. Immediate early genes were shown to form part of the signal transduction cascade from the cell surface to the nucleus leading to long-term changes in structure and function (i.e. plastic changes) and hence were given the title of "*third messengers*" [4] (fig. 1). Studies using Fos showed that its appearance could be used to mark those cells that had been stimulated and activated [5]. Indeed Fos expression has been used to map pathways of activation after various types of peripheral stimulation and generally shows good correlation with known anatomical pathways, for example Fos activation in the spinal cord and brain after noxious stimulation matches known routes which carry pain sensation [6]. As Fos activation can be seen only if sufficient stimulation has occurred in a cell, then it is obvious that Fos activation can be used not only to map metabolic activity in cells but also the effectiveness of therapies to suppress the activity of cells, for example to examine the efficacy of drugs such as those that may prevent secondary brain injury, antiepileptics and analgesics. One advantage of Fos expression over standard neurophysiological techniques is that the responses of large numbers of cells can be assessed as one may examine a whole section of brain or spinal cord for Fos protein or mRNA.

In this issue of the journal, Sun, Shyu and Shieh [2] show that 2% halothane with or without nitrous oxide and the μ agonist, fentanyl, reduced pain-related behaviour in response to painful stimulation but fentanyl alone reduced Fos expression in the spinal cord. The study raises a number of points.

(1) Using Fos expression as an index, volatile agents and nitrous oxide are not adequate analgesics for painful stimulation. However, one could argue that as long as the subject is anaesthetized with the volatile agent and not apparently responding, does it matter that peripheral stimulation reaches the spinal cord and the brain and causes Fos expression? To answer this point we need to know if there is any evidence that using different types of anaesthetic regimens can have long-term consequences for the individual.

(2) Even the large dose of fentanyl only reduced Fos expression by up to 50% in this study, that is significant Fos expression still occurred; if Fos expression were associated with deleterious physiological effects, should we be using other techniques or agents that are more effective at suppressing Fos expression than opioids?

Regarding the first point, there is increasing evidence that pain intensity and duration in acute and chronic pain models can be reduced and perhaps prevented if painful stimulation is impeded from reaching the cord either by the use of prior local anaesthesia or systemic analgesics but not by volatile agents alone [7–9]. In one study, different types of analgesic regimens were tested for their ability to

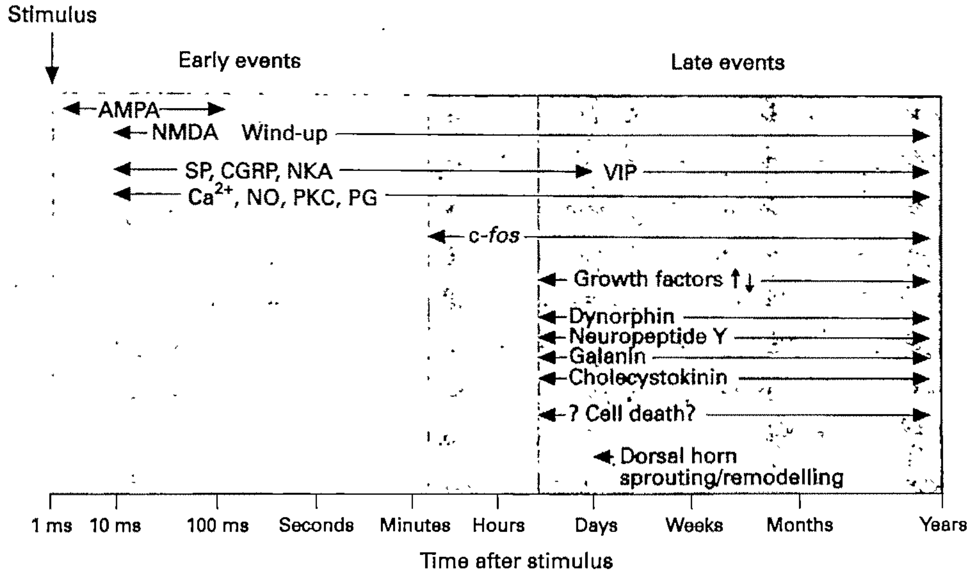

Figure 1 Schematic and partially speculative diagram outlining the cascade of molecular events which may follow peripheral nerve injury or stimulation, which attempts to place in context the role of *c-fos* in this cascade. Some of the changes only occur in certain situations, for example VIP and cholecystokinin are upregulated after peripheral nerve injury but not after inflammatory injury, while others show opposite changes, for example SP increases in inflammatory pain states but decreases after nerve injury. However, many changes are common to both pain states, for example activation of the NMDA channel, increase in intracellular Ca^{2+}, involvement and upregulation of neuronal nitric oxide synthase and increase in *c-fos*. Dynorphin and NPY increases have also been described in both types of pain, and there is some evidence that *c-fos* may lead to their activation. These changes in ion channel function, second messengers, immediate early genes such as *c-fos* ("third messengers") and neuropeptides may then be followed by more permanent changes in the nervous system consisting of changes in synaptic efficacy of pre-existing synapses, nerve sprouting and formation of novel synapses to which *c-fos* may also contribute via growth factors. We speculate that these latter changes may be the basis of pain memories in the spinal cord and brain. There is some evidence that inhibiting the earlier events may delay and perhaps prevent some of the later events, that is prevent the formation of long-term changes which are associated with persistent pain. For further general discussions see [10, 11, 31, 32, 35–40] and references within. AMPA = alpha-amino-3-hydroxy-5-methyl-isoxazole, NMDA = *N*-methyl-D-aspartate, SP = substance P, CGRP = calcitonin gene-related peptide, NKA = neurokinin A, NO = nitric oxide, PKC = protein kinase C, PG = prostaglandins, VIP = vasoactive intestinal polypeptide. Figure redrawn and modified from [41].

prevent the development of a chronic pain state after nerve injury [10]. The use of isoflurane alone was compared with isoflurane with either morphine, an α_2 agonist (clonidine) or an NMDA antagonist (MK-801). Volatile agent alone or morphine pretreatment was not as effective as pretreatment with clonidine or MK-801 in preventing chronic pain behaviour and associated changes in the spinal cord and dorsal root ganglia. Yet all of the regimens seemed equally effective at producing an apparently satisfactory state of anaesthesia at the time of nerve injury. Other studies have shown that α_2 agonists or NMDA antagonist are, in general, more effective than opioids in suppressing Fos expression after peripheral stimulation, although the type of stimulation used is an important factor [11]. Thus the efficacy of analgesics to suppress Fos parallels their ability to prevent the development of a chronic pain state.

Timing of the analgesia is also critical. In acute and chronic pain models, the application of local or systemic analgesia *after* painful stimulation is neither effective in preventing acute or chronic pain nor in suppressing the Fos response [9, 12], hence the concept of pre-emptive analgesia is again supported by these studies. In humans unfortunately, the case for prior administration of analgesics is not as clear-cut; there are only a few clinical studies showing that pre-emptive use of analgesics provides a reduction in subsequent pain perception [9, 13–20]. This is puzzling and yet, as we have suggested previously, analysis of Fos expression may provide some clues [21]. Even very high-dose opioids are not as efficacious as other analgesics in preventing Fos expression and subsequent pain [2, 10, 22, 23]. As clinical studies examining pre-emptive analgesia often use opioids, it may not be that surprising that the pre-emptive analgesia effect is often small or not significant. Another reason may be that again, as suggested previously [21], the duration of the injury outlasts the effective analgesia, for example local anaesthetic block may have worn off while the discharge from the sensitized primary afferent fibres continues minimizing the beneficial effect of the original procedure (see [24–26]).

On one level, Fos can be used simply as a marker of nociception but recent studies have made physiological consequences of Fos expression clearer. Fos may act on many genes to cause their expression, including that of preprodynorphin, neuropeptide Y (NPY) and nerve growth factor [4]. Both dynorphin and NPY have analgesic properties and so Fos may not only signal the magnitude of the insult reaching the spinal cord but also mediate some of its adaptive responses to it. In fact, one can now envisage a cascade of molecular events in the spinal cord after peripheral stimulation leading eventually to permanent structural changes within the nervous system (see fig. 1) [27–32].

In summary, the findings of Sun, Shyu and Shieh and other studies are as follows [2, 9–12, 22].

(1) An anaesthetic regimen based solely on oxygen–nitrous oxide and a volatile agent is not sufficient analgesia for painful stimulation despite the fact that during the procedure there may be no obvious subjective responses. In fact, as far as the spinal cord is concerned, it is totally unprotected against these painful insults which may have consequences for the perception of acute postoperative pain and the development of chronic pain states.

(2) Although most anaesthetists do provide some analgesia at some stage of the operation, pre-emptive local anaesthetic block or analgesic administration which is then continued into the postoperative period is likely to be most beneficial.

(3) The differential effects of various analgesics on Fos expression suggest that the use of other analgesics (such as clonidine, an α_2 agonist, and ketamine, an NMDA antagonist) should be considered, certainly as adjuncts to morphine.

Suggestions that providing operating conditions in which the transmission of peripheral stimulation into the central nervous system is impeded are not new [33, 34]. However, as we have suggested previously, studies using Fos expression in the spinal cord may provide a more rational basis in designing novel pre-emptive anaesthetic regimens.

CLINICAL INVESTIGATIONS

Dobutamine increases oxygen consumption during constant flow cardiopulmonary bypass

W. Karzai, A. Lötte, M. Günnicker, U. M. Vorgrimler-Karzai and H.-J. Priebe

Summary

We have studied the effects of flow and dobutamine on systemic haemodynamic variables, oxygen delivery ($D\text{O}_2$) and oxygen consumption ($\dot{V}\text{O}_2$) in 20 patients during cardiopulmonary bypass (CPB) with mild hypothermia (34 °C). In a subgroup of seven patients, we also studied the effects on gastric microcirculatory blood flow (MCF) using laser Doppler flowmetry. During CPB, measurements were made before and after two interventions: the first consisted of increasing flow from 2.4 to 3.0 litre $\text{min}^{-1}\ \text{m}^{-2}$ for 10 min; the second consisted of an infusion of dobutamine at a rate of 6 $\mu\text{g kg}^{-1}\ \text{min}^{-1}$ for 10 min during constant flow CPB. There were no significant differences in $D\text{O}_2$, $\dot{V}\text{O}_2$ or haemodynamic variables between the two baseline measurements. The increase in flow raised $D\text{O}_2$ (27%, $P < 0.001$), mean arterial pressure ($P < 0.01$) and MCF ($P < 0.01$), but failed to increase $\dot{V}\text{O}_2$. In contrast, dobutamine infusion increased $\dot{V}\text{O}_2$ (11%, $P < 0.001$) during constant flow CPB without significant changes in $D\text{O}_2$, systemic haemodynamic variables or MCF. These results indicate that increases in $\dot{V}\text{O}_2$ during dobutamine may be flow-independent. (*Br. J. Anaesth.* 1996; **76**: 5–8)

Key words

Heart, dobutamine. Heart, cardiopulmonary bypass. Oxygen, consumption.

The synthetic catecholamine, dobutamine, is frequently used in critically ill patients to increase cardiac output and oxygen delivery ($D\text{O}_2$) [1, 2]. Normally, changes in cardiac output or $D\text{O}_2$ only minimally influence systemic oxygen consumption ($\dot{V}\text{O}_2$) [3]. However, in pathological states, $\dot{V}\text{O}_2$ is presumed to become delivery-dependent [3], possibly because of an increase in flow and $D\text{O}_2$ to less well perfused areas of the circulation. Dobutamine infusion has been used in critically ill patients, not only diagnostically to uncover delivery-dependent $\dot{V}\text{O}_2$, but also therapeutically to increase perfusion to less well perfused areas of the organism [1, 2, 4].

Several studies have reported an increase in metabolic rate during various catecholamine infusions [5–8]. These studies suggest that at least part of the increase in $\dot{V}\text{O}_2$ infusion may be explained by the calorigenic effect of the catecholamine, unrelated to increases in flow or $D\text{O}_2$. In healthy humans, dobutamine has been shown to increase $\dot{V}\text{O}_2$ [8, 9]. However, the increase in $\dot{V}\text{O}_2$ was accompanied by an increase in cardiac output, thus not conclusively demonstrating flow-independent increases in $\dot{V}\text{O}_2$. Accordingly, the aim of this study was to study the flow-independent effects of dobutamine on $\dot{V}\text{O}_2$ and contrast them with the effects of flow on $\dot{V}\text{O}_2$. This was done using cardiopulmonary bypass (CPB) which, as we and others have shown [10–13], provides a means of studying the flow-independent effects of various interventions during constant flow without compromising patient safety. As redistribution of blood flow to metabolically active but underperfused areas of the circulation may increase $\dot{V}\text{O}_2$, even in the presence of unchanged flow, in addition we studied the effects of flow and dobutamine on the gastric microcirculation to uncover possible redistribution of blood to this area of the circulation.

Patients and methods

We studied 20 patients requiring CPB during cardiac surgery. The Ethics Committee of Essen University approved the study and all patients gave informed consent.

All patients received flunitrazepam 2 mg approximately 1 h before arriving in the operating room. An arterial catheter and a flow-directed pulmonary artery catheter were inserted under local anaesthesia. General anaesthesia was induced with etomidate 0.15–0.30 mg kg^{-1}, and fentanyl 5–7 $\mu\text{g kg}^{-1}$, followed by pancuronium 0.1 mg kg^{-1} and was maintained with 0.4–0.6 vol % isoflurane and 50 % nitrous oxide in oxygen. During operation and before CPB, increments of fentanyl 0.25 mg, pancuronium 2 mg and flunitrazepam 0.2 mg were given as needed. Fentanyl 0.25 mg and pancuronium 4 mg were added to the prime, and 0.4 vol % isoflurane was maintained during CPB. Extracorporeal circulation was maintained using non-pulsatile pump flow (Stöckert, Munich, Germany) at a standard flow rate of 2.4 litre $\text{min}^{-1}\ \text{m}^{-2}$. Oxygenation was provided

by a Cobe CML membrane oxygenator (Laboratories GmbH, Heimstetten, Germany). An asanguineous prime containing 1000 ml of lactated Ringer's solution, 10% hydroxyethylstarch 500 ml, 20% mannitol 100 ml and 8.4% sodium bicarbonate 100 ml was used. Packed cell volume was maintained above 20%. Blood temperature was kept at 34 °C. Measurements were made after CPB was commenced, the aorta was cross-clamped, the heart was in hypothermic cardioplegic arrest, and rectal and nasopharyngeal temperatures were within 0.8 °C of each other.

In seven of the 20 patients, gastric microcirculatory blood flow was studied using laser Doppler flowmetry (LDF) (MBF 3D, Moors Instruments Ltd, Devon, England). The measurement probe (fibreoptic wire < 3 mm ϕ) was inserted through the lumen of a nasogastric tube. The correct position of the nasogastric tube was confirmed by auscultation and aspiration of gastric contents. The correct position of the probe was verified by observing typical pulse synchronous oscillations. LDF uses the size and amount of the frequency shift caused by the back-scattered laser beam to calculate microcirculatory blood flow (MBF) [14]. LDF has been used experimentally to measure intestinal mucosal blood flow and has been found to correlate with mucosal blood flow, as measured by standard techniques [15].

Initial measurements were made at a flow rate of 2.4 litre min^{-1} m^{-2} (baseline 1). Flow was then increased to 3.0 litre min^{-1} m^{-2} (intervention 1), and repeat measurements were made 10 min later. Flow was then returned to and maintained at 2.4 litre min^{-1} m^{-2}, and measurements were repeated 5 min later (baseline 2). Subsequently, at unchanged flow, dobutamine 6 µg kg^{-1} min^{-1} was started (intervention 2), and repeat measurements were made 10 min later. At each of these times, samples were obtained for blood-gas analysis, and electrolyte and blood glucose concentrations from sampling ports of the CPB cannulae, and haemodynamic variables were recorded. Samples for blood-gas analysis were analysed immediately at 37 °C. $D\text{O}_2$ and $\dot{V}\text{O}_2$ were calculated according to the Fick method.

A repeated measures analysis of variance was used to test for differences between times. Paired *t* tests, corrected for multiple comparisons (Bonferroni), were used to test for differences between each baseline and subsequent intervention, and between the two baseline values [16]. Statistical significance was based on *P* values less than 0.05. Results are presented as mean (SD). The statistical program used was SAS (SAS Institute Inc., Cary, NC, USA) on an Accel (486DX33) Notebook computer (Accel Computers, Rockville, MD, USA).

Results

Patient data are summarized in table 1.

The increase in CPB flow rate from 2.4 to 3.0 litre min^{-1} m^{-2} significantly increased $D\text{O}_2$, mean arterial pressure (MAP) and gastric MCF, and decreased oxygen extraction (table 2). $\dot{V}\text{O}_2$ did not change significantly. In contrast, dobutamine 6 µg kg^{-1} min^{-1} for 10 min increased $\dot{V}\text{O}_2$ and oxygen extraction but MBF remained unchanged (table 2). Plasma concentrations of glucose and potassium were not affected by the two interventions. There were no significant differences in rectal temperature during the procedure (table 3).

Discussion

In this study, we found that dobutamine, in clinical doses, increased $\dot{V}\text{O}_2$. This increase occurred in the presence of unchanged global and regional gastric mucosal flow and $D\text{O}_2$.

This finding of an increase in $\dot{V}\text{O}_2$ during dobutamine is in agreement with previous studies. In healthy volunteers, dobutamine 5–10 µg kg^{-1} min^{-1} was found to increase energy expenditure or $\dot{V}\text{O}_2$ by 20–33% [8, 9]. However, in these studies cardiac output (flow) presumably or measurably increased, whereas in our study flow was controlled. The smaller increase in $\dot{V}\text{O}_2$ (11%) found in our study may have been caused by a lack of increase in myocardial oxygen consumption, a lack of increase in total body blood flow in response to dobutamine, a higher basal catecholamine concentration during CPB [17] or by hypothermia.

We cannot explain why dobutamine increased $\dot{V}\text{O}_2$ without changing global blood flow. Flow-independent increases in $\dot{V}\text{O}_2$ in response to catecholamines may be caused by direct effects on effector cells, indirect effects on humoral factors (insulin and glucagon) or redistribution of blood flow, resulting in increased perfusion of metabolically active tissues [18]. The effects of catecholamines on metabolism are frequently accompanied by an increase in glucose and a decrease in potassium concentration [18]. This did not occur in our study. Redistribution of flow to less well perfused regions of the circulation could have been responsible for the increase in $\dot{V}\text{O}_2$. However, whereas the increase in flow (i.e. first intervention) increased MBF to one area of the circulation but failed to increase $\dot{V}\text{O}_2$, dobutamine failed to increase gastric MBF. These findings would suggest that redistribution of blood flow is unlikely to be a major cause of the increase in $\dot{V}\text{O}_2$ with dobutamine. In contrast, in a previous study using a similar design, dopamine increased gastric MBF without increasing $\dot{V}\text{O}_2$ [13]. However, some of the observed differences between dobu-

tamine and dopamine on gastric blood flow may be caused by different receptor activities of these catecholamines on regional and systemic vasculature.

Randomization of the sequence of interventions (i.e. flow variation and dobutamine infusion) might have been preferable. However, as there are no data on the clearance of dobutamine during hypothermia, we chose not to randomize the sequence of interventions. The similar values before flow intervention and before dobutamine infusion are evidence of the stability of this model and return to baseline conditions after flow intervention.

As neuromuscular block is known to decrease $\dot{V}O_2$ [19], a possible decrease in block during the study might have affected the changes in $\dot{V}O_2$. However, as hypothermic CPB has been shown to reduce requirements [20] and increase the duration of action of pancuronium [21], and as pancuronium 4 mg was added to the prime of the extracorporeal circuit, it is highly unlikely that a decrease in neuromuscular block occurred during the study.

Even acknowledging the limitations of this study (i.e. hypothermia and surgical procedure with humoral activation), our finding may have implications for the diagnostic and therapeutic uses of dobutamine. Dobutamine has been used diagnostically in critically ill patients to increase DO_2 and uncover delivery-dependent $\dot{V}O_2$ [4]. As we have observed that dobutamine increased $\dot{V}O_2$, independent of DO_2, this diagnostic test may be of limited value. Furthermore, dobutamine has been used therapeutically to increase DO_2 and achieve supranormal values of $\dot{V}O_2$ in haemodynamically stable but critically ill patients in the hope of possibly increasing survival [22]. Our findings suggest caution in using dobutamine for this purpose. Dobutamine may further increase $\dot{V}O_2$, independent of increases in DO_2 or cardiac output (flow), and thus unnecessarily increase heart work and $\dot{V}O_2$, and possibly endanger the patient. A recent study suggested that increasing $\dot{V}O_2$ with dobutamine to achieve supranormal values in critically ill patients may increase mortality [23].

Effects of sevoflurane and isoflurane on systemic vascular resistance: use of cardiopulmonary bypass as a study model

G. RÖDIG, C. KEYL, G. WIESNER, A. PHILIPP AND J. HOBBHAHN

Summary

We have examined the dose-related effects of sevoflurane and isoflurane on systemic vascular resistance (SVR) during cardiopulmonary bypass (CPB) in patients undergoing elective coronary artery surgery. Fifty-two patients were allocated randomly to one of six groups to receive 1.0, 2.0 or 3.0 vol% (inspiratory) sevoflurane or 0.6, 1.2 or 1.8 vol% isoflurane, or to a control group. During hypothermic (32–33 °C) non-pulsatile CPB, systemic vascular resistance index (SVRI) was recorded before administration of volatile anaesthetics and every 5 min for 20 min. Sevoflurane and isoflurane concentrations were measured next to the gas inlet port and at the gas outlet port of the oxygenator. Wash-in of sevoflurane occurred more rapidly than that of isoflurane, reaching a relatively steady state for both agents from the 10th to the 20th min. There was no significant change in SVRI in patients receiving 1.0 and 2.0 vol% sevoflurane, and 0.6 and 1.2 vol% isoflurane, compared with baseline values. However, 3 vol% sevoflurane decreased SVRI at 10, 15 and 20 min, and 1.8 vol% isoflurane decreased SVRI significantly at 15 and 20 min, whereas SVRI increased at 15 and 20 min in the control group. Thus during CPB, sevoflurane had similar vasodilator effects on SVRI as isoflurane. (*Br. J. Anaesth.* 1996; **76**: 9–12)

Key words

Heart, cardiopulmonary bypass. Anaesthetics volatile, isoflurane. Anaesthetics volatile, sevoflurane. Cardiovascular system, effects.

Studies comparing the cardiovascular effects of isoflurane with sevoflurane in surgical ASA I and II patients found similar changes in mean arterial pressure [1–4]. The decrease in arterial pressure caused by sevoflurane may result from depression of myocardial contractility and decreased peripheral vascular resistance [5]. As there are only few data available in volunteers focusing on the influence of sevoflurane on systemic vascular resistance (SVR) [6], we administered sevoflurane during cardiopulmonary bypass (CPB) and compared its effects with those of isoflurane. CPB is considered a useful model for studying the isolated effects of drugs on the systemic vasculature, as cardiac effects are excluded during aortic cross-clamping [7–13].

Patients and methods

After obtaining written informed consent, we studied 52 patients (35 male), median age 67 yr (range 36–80 yr), undergoing elective coronary artery surgery. The study was approved by the local Ethics Committee. Patients were excluded if they had a history of central nervous system disease, significant renal or hepatic impairment, peripheral vascular disease or an ejection fraction of < 50%.

Patients were premedicated with clorazepate 20–30 mg orally on the evening before surgery, and clorazepate 20 mg approximately 1 h before operation. All patients received their routine anti-anginal and antihypertensive medication up to and including the morning of surgery. Anaesthesia was induced with fentanyl 5 μg kg^{-1} i.v., followed by a sleep dose of etomidate. Neuromuscular block was produced with pancuronium 100 μg kg^{-1}. Anaesthesia was maintained before CPB with an infusion of propofol 5 mg kg^{-1} h^{-1}, supplemented with fentanyl bolus doses up to 20 μg kg^{-1} and pancuronium 50 μg kg^{-1}.

A standard CPB technique was used in all patients. Before aortic cannulation patients were anti-coagulated with heparin (375 u. kg^{-1}). The bypass circuit consisted of a capillary membrane oxygenator (Maxima/plus, Medtronic, Anaheim, CA, USA) and a roller pump (Stöckert Instruments, Munich, Germany), which was primed with a crystalloid solution. A hard-shell venous reservoir, open to air, was used, with an integral cardiotomy reservoir.

The 52 patients were allocated randomly to one of six groups of seven patients, or to a control group of 10 patients. After application of the aortic cross-clamp and administration of cold cardioplegic solution (Kardioplegische Perfusionslösung Fresenius, Bad Homburg, Germany), time was allowed to develop a stable level of perfusion pressure and mild hypothermia (arterial and bladder temperatures 32–33 °C). These variables remained constant for at least 10 min before initiating the test sequence. Baseline values were recorded at the end of the stabilization period. Thereafter, patients allocated to group 1 received 1.0 vol% sevoflurane, group 2, 0.6

GABRIELE RÖDIG, MD, CORNELIUS KEYL, MD, GUNTHER WIESNER, MD, ALOIS PHILIPP, JONNY HOBBHAHN, MD, University Hospital, Department of Anaesthesiology, Franz-Josef-Strauss-Allee 11, 93042 Regensburg, Germany. Accepted for publication: July 26, 1995.

Correspondence to G.R.

vol % isoflurane, group 3, 2.0 vol % sevoflurane, group 4, 1.2 vol % isoflurane, group 5, 3.0 vol % sevoflurane and group 6, 1.8 vol % isoflurane, the volatile anaesthetics being administered via a vaporizer inserted into the oxygenator gas supply line with a constant gas flow of 3 litre min^{-1}. Patients in the control group received no volatile anaesthetic or additional i.v. anaesthetic during the study. Anaesthetic gas concentrations were measured for both sevoflurane and isoflurane with a Datex multiple gas analysis monitor (Capnomac Ultima, Hoyer, Bremen, Germany) next to the gas inlet port of the oxygenator, and were adjusted continuously to "inspiratory" values. Gas concentrations of both agents were measured also at the gas outlet port of the oxygenator.

Non-pulsatile perfusion and alpha-stat acid–base management were used. Pump flows were 2.4 litre min^{-1} m^{-2} throughout the study. Packed cell volume was determined at the beginning and end of the test sequence. The time available for study at stable hypothermia was 20 min.

Systemic arterial pressures, measured via a femoral artery cannula, were monitored continuously throughout the procedure and, at the end of each 5-min period, recordings were made of mean arterial pressure (MAP). Systemic vascular resistance (SVR) was calculated from MAP (mm Hg) and pump flow rate, $\dot{Q}$ (litre min^{-1}) as: $SVR = (MAP/\dot{Q}) \times 80$ (dyn s cm^{-5}). Systemic vascular resistance index (SVRI) was equal to SVR × body surface area (BSA). Hypotension during CPB requiring intervention was defined as MAP < 35 mm Hg and hypertension as MAP > 90 mm Hg. When intervention became necessary patients were withdrawn from the study.

All data are presented as median (range). Differences between changes in SVRI from baseline values and time-dependent changes in the ratio of exhaust gas to inspired anaesthetic concentrations were tested using the Friedmann two-way analysis of variance followed by the Wilcoxon and Wilcox test for repeated measurements. $P < 0.05$ was considered significant.

Results

There were no significant differences between the groups in age, weight, body surface area or preoperative medication. The groups did not differ in intraoperative medications before the study.

Figure 1 shows the ratio of exhaust gas anaesthetic concentrations (*F*E) to inspired anaesthetic concentrations (*F*I) at times when SVRI was recorded. We present pooled data from groups 1, 3 and 5 (1, 2 and 3 vol % sevoflurane) and 2, 4 and 6 (0.6, 1.2 and 1.8 vol % isoflurane) to illustrate the pharmacokinetics during wash-in of both volatile anaesthetics, as there were no significant differences in *F*E/*F*I between 1, 2, 3 vol % sevoflurane or between the three isoflurane groups. *F*E/*F*I for sevoflurane increased more rapidly than for isoflurane, reaching a median equilibration after 20 min of 68 % (range 62–80 %) for sevoflurane and of 49 % (36–60 %) for isoflurane. *F*E/*F*I at 5 min was significantly different for both the sevoflurane and isoflurane curves compared with *F*E/*F*I ratios after 10, 15 and 20 min, whereas there was no change in *F*E/*F*I between the 10-, 15- and 20-min values for both drugs.

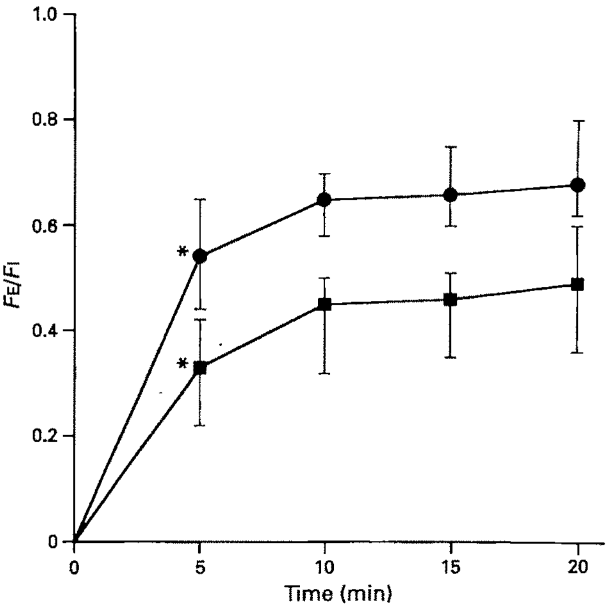

Figure 1 Ratio of exhaust gas concentrations (*F*E) to inspired anaesthetic concentrations (*F*I) (median, range) during washin of sevoflurane (●) and isoflurane (■). $*P < 0.05$ *vs* 10, 15 and 20 min.

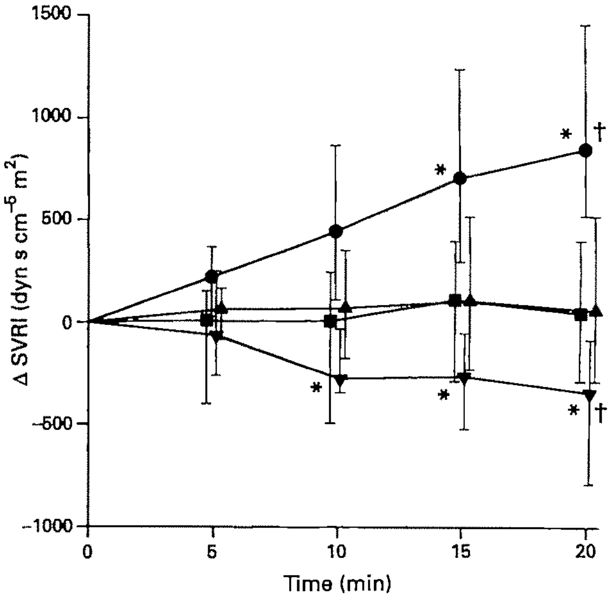

Figure 2 Changes in systemic vascular resistance index (SVRI) from baseline values (median, range) in 1.0 vol % (■), 2.0 vol % (▲) and 3.0 vol % (▼) sevoflurane treated and control (●) patients. $*P < 0.05$ *vs* 0 min; $\dagger P < 0.05$ *vs* 5 min.

Figure 2 presents the changes in SVRI from baseline values in those patients treated with sevoflurane and in the control group. There was no significant change in SVRI at any time in those patients receiving 1.0 and 2.0 vol % sevoflurane. In the 3.0 vol % sevoflurane group, significant changes in SVRI were observed at 10, 15 and 20 min compared with the baseline value, and at 20 min compared with the 5-min value.

In patients receiving 0.6 and 1.2 vol % isoflurane, there was no difference in SVRI with time (fig. 3),

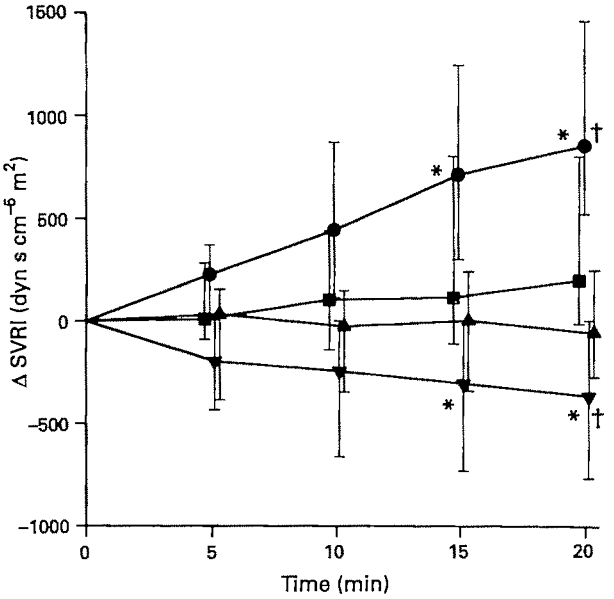

Figure 3 Changes in SVRI from baseline value (median, range) in 0.6 vol% (■), 1.2 vol% (▲) and 1.8 vol% (▼) isoflurane treated and control (●) patients. $*P < 0.05$ *vs* 0 min; $\dagger P < 0.05$ *vs* 5 min.

that is SVRI was maintained equally at baseline in these two groups. There were significant decreases in SVRI in the 1.8 vol% isoflurane group compared with baseline values at 15 and 20 min. The 20-min value also differed significantly from the 5-min value. In contrast, in the control group there was a significant increase in SVRI at 15 and 20 min compared with baseline values, and also at 20 min compared with the 5-min values. The change in SVRI, expressed as a percentage change from baseline values, at 15 min was −16% (median) for 3.0 vol% sevoflurane (range −3 to −22%) compared with −20% (0 to −35%) for 1.8 vol% isoflurane; at 20 min changes of −24% (−5 to −35%) for 3.0 vol% sevoflurane and of −24% (0 to −42%) for 1.8 vol% isoflurane were noted. The increase in SVRI in the control group, expressed as a percentage change from baseline, corresponded to an increase of 50% (+28 to +108%) at 15 min and to an increase of 66% (+49 to +127%) at 20 min.

Hypotension or hypertension requiring intervention occurred in none of the 42 patients treated with sevoflurane and isoflurane. However, two patients in the control group were excluded because of hypertension (MAP > 90 mm Hg). Packed cell volume did not change in any patient during the 20-min study.

Discussion

Volatile anaesthetics are known to induce hypotension because of effects on the central and autonomic nervous system, on the myocardium and because of a direct action on vascular smooth muscle. To exclude myocardial effects, we administered sevoflurane and isoflurane during CPB, as cardiac responses need not to be considered during aortic cross-clamping. This situation has been used as a model by others interested in the vasoactive properties of anaesthetic agents such as propofol [7,8], diazepam [9], thiopentone [10], etomidate [10], droperidol [11], isoflurane [12,13] or halothane [13].

We administered 1.0, 2.0 and 3.0 vol% "inspiratory" sevoflurane and 0.6, 1.2 and 1.8 vol% isoflurane over a 20-min period. Sevoflurane 2.0 vol% [14] and 1.2 vol% isoflurane correspond to approximately 1 MAC.

Wash-in of the volatile anaesthetics occurred in a cold phase with arterial blood and bladder temperatures maintained at 32–33 °C. Relative to isoflurane, *F*E/*F*I increased more rapidly with sevoflurane. The partition coefficient in undiluted normothermic blood is 0.65 for sevoflurane and 1.4 for isoflurane [14]. Similar differences may be assumed during hypothermic CPB because of the counterbalancing effects of haemodilution and hypothermia on blood-gas partition coefficients [15]. As observed by Nussmeier and colleagues [16], we found that wash-in of volatile anaesthetics occurred more slowly during CPB than would be expected from the pharmacokinetic data of drugs administered via the lungs in normothermic patients [17]. After an initial rapid increase there were no significant changes in *F*E/*F*I ratios from 10 to 20 min for both agents, indicating a relatively steady state.

We calculated SVRI from MAP, a fixed pump flow rate and body surface area. As venous drainage was adequate at all times, we assumed that central venous pressure was zero. The venous reservoir volume did not reflect changes in capacitance vessels as we used a venous reservoir with an integral cardiotomy reservoir.

We did not find significant changes in SVRI from baseline over the 20-min period with 1.0 and 2.0 vol% sevoflurane. The same time course in ΔSVRI, with no difference from baseline values over 20 min, was obtained when anaesthesia was maintained with 0.6 and 1.2 vol% isoflurane, whereas SVRI increased significantly compared with baseline at 15 and 20 min in the control group. Two patients in this group had to be withdrawn from the study as MAP exceeded 90 mm Hg. This increase in SVRI reflects the usual pattern of SVR increasing during hypothermic non-pulsatile CPB, which probably results from a marked stress response, as indicated by increases in adrenaline, noradrenaline [18,19] and arginine vasopressin [20]. Mediators such as thromboxane may also play a role [21].

Vasodilatation capacity was evident by the decrease in SVRI with higher concentrations of sevoflurane and isoflurane. Inspiratory concentrations of 3 vol% sevoflurane and 1.8 vol% isoflurane reduced SVRI significantly 10 min after commencing sevoflurane and after 15 and 20 min for both drugs compared with baseline values. The finding that SVRI and, thus, perfusion pressure decreased significantly during administration of 1.5 MAC of sevoflurane and isoflurane implies that both agents caused arteriolar vasodilatation.

Hence, we found that sevoflurane in low, medium and higher inspiratory concentrations had similar effects on SVRI as those of isoflurane. Our results are in accordance with the findings of Malan and colleagues [22] who showed that the changes in SVR were qualitatively similar to those of isoflurane.

Vasodilatation may be attributed to the direct relaxant actions on vascular smooth muscle [23, 24], reduction in sympathetic output [25] or reduction in the effectiveness of other stimuli on the vascular smooth muscle. The precise mechanisms cannot be identified in the complex clinical situation.

Cardiopulmonary bypass with modified fluid gelatin and heparin-coated circuits

P. G. M. JANSEN, H. TE VELTHUIS, W. R. WILDEVUUR, M. A. J. M. HUYBREGTS, E. R. BULDER, H. I. VAN DER SPOEL, A. STURK, L. EIJSMAN AND C. R. H. WILDEVUUR

Summary

We have assessed the efficacy of cardiopulmonary bypass (CPB) using normal colloid oncotic pressure (COP) in a randomized, controlled study of 20 patients undergoing elective coronary artery surgery using heparin-coated circuits. For CPB, we used either crystalloid priming 1650 ml ($n = 10$) or colloid priming 1650 ml (2.4% modified fluid gelatin, $n = 10$). While COP did not change during bypass in the colloid group, a decline was observed in the crystalloid group ($P = 0.005$). By the end of bypass, the decrease in COP compared with baseline (ΔCOP) was 8.5 (S.D. 1.1) mm Hg in the crystalloid group compared with 1.5 (2.1) mm Hg in the colloid group ($P = 0.0001$). ΔCOP correlated positively with fluid balance during bypass ($r^2 = 0.41$, $P = 0.002$). Similar increments in complement factors C3b/c and C4b/c, tumour necrosis factor-α and neutrophil elastase, but not endotoxins, were found in both groups as indicators of a systemic inflammatory response. A clinical performance score composed of fluid balance, postoperative duration of intubation and the difference between rectal temperature and skin temperature was more favourable in patients treated with colloid priming ($P = 0.03$). Median postoperative hospital stay was 7 (range 5–16) days in the crystalloid group compared with 5 (4–8) days in the colloid group ($P = 0.016$). Regression analysis indicated that CPB time, fluid balance during operation and postoperative $P\text{O}_2/F\text{I}_{\text{O}_2}$ ratio were independent factors that predicted postoperative hospital stay. From these preliminary results we conclude that in the absence of endotoxaemia, use of a normal COP during CPB with modified fluid gelatin in heparin-coated circuits resulted in an improved postoperative course an a reduction in hospital stay. (*Br. J. Anaesth.* 1996; **76**: 13–19)

Key words

Heart, cardiopulmonary bypass. Blood, colloid oncotic pressure.

In adult cardiac surgery, haemodilution with clear priming solutions has become established clinical practice. If crystalloids primarily are used in the circuit priming, a sudden decrease in serum colloid oncotic pressure (COP) occurs after beginning cardiopulmonary bypass (CPB) [1, 2]. This leads to extravasation of fluids, with oedema formation and weight gain [3, 4]. Colloid-containing priming solutions are advocated to prevent the initial decrease in COP at the beginning of CPB. However, studies comparing crystalloid with colloid priming solutions were carried out with large priming volumes and failed to achieve a normal COP during CPB. The marginal clinical benefits observed fostered the controversy regarding the optimal prime composition [5–7].

The systemic inflammatory response that is characteristically observed after CPB may also contribute to increased microvascular permeability and hence a fluid shift towards the interstitial space. Exposure of blood to the artificial surfaces of the extracorporeal circuit activates host defence mechanisms [8, 9], while splanchnic hypoperfusion during CPB has been associated with intestine-derived endotoxin migration into the circulation [10]. Both phenomena result in release of inflammatory mediators and therefore also alter endothelial integrity.

Recently, several clinical studies reported that there was less complement activation products and, subsequently, a smaller systemic inflammatory response when heparin-coated circuits were used for CPB [11–13]. The present study was conducted to investigate if in patients treated with low-prime heparin-coated circuits, use of a normal COP by colloid priming elicits further benefits on the systemic inflammatory response, postoperative clinical performance and hospital stay.

Patients and methods

We studied 20 patients undergoing first-time coronary artery surgery. Study entry criteria coincided with the 80 % central range of the elective first-time coronary artery bypass grafting population at the

study hospital: age 45–75 yr and preoperative left ventricular end-diastolic pressure 10–35 mm Hg. Patients receiving acetylsalicylic acid in the 3 days before operation, those with preoperative coagulopathy or impaired organ function other than myocardial ischaemia and those receiving anti-inflammatory drugs were excluded. The patients were allocated randomly to one of two groups: 10 patients with crystalloid prime and no infusion of colloids during CPB (crystalloid group) and 10 patients with colloid-containing prime and infusion of colloids during CPB (colloid group). Except for the perfusionists, the clinical team was blinded to the randomization. Written informed consent was obtained from each patient and the study was approved by the Medical Ethics Committee of the Free University Hospital.

CHOICE OF COLLOID

In the study hospital, modified fluid gelatin (MFG, Gelofusine, NPBI BV, Emmer-Compascuum, Netherlands) is used as standard plasma substitute. Modified fluid gelatin (MFG) is prepared by alkaline hydrolysis and succinylation of bovine bone collagen. The weight average molecular weight of MFG is 35000 Da and the number average molecular weight is 22600 Da. Gelatin molecules are excreted mainly by glomerular filtration. The volume effect of MFG lasts 3–4 h, whereas its overall survival in blood is 168 h. Significant anaphylactic reactions to MFG occur in 1:6000 to 1:13000 u. administered, a ratio similar to other colloids [14]. MFG is presented as a 500-ml isotonic 4% solution and exerts a COP of 56 mm Hg to a 10000 Da membrane (Onkometer BMT 921, BMT Messtechnik GmBH, Berlin, Germany).

ANAESTHESIA AND CARDIOPULMONARY BYPASS

On the morning of surgery, patients received their usual early morning dose of antianginal medication and lorazepam 5 mg. Anaesthesia was induced with sufentanil 3 μg kg^{-1} i.v., pancuronium 0.1 mg kg^{-1} i.v. and midazolam 0.1 mg kg^{-1} i.v., and maintained with supplementary doses of these drugs. Cefuroxime 1.5 g was given i.v. for infection prophylaxis. After tracheal intubation, the lungs were ventilated to normocapnia using an oxygen–air mixture. Radial artery and thermodilution pulmonary artery catheters were inserted for haemodynamic measurements and obtaining blood samples. Fluid infusion before CPB consisted of MFG (500 ml maximum) and 0.9% NaCl (500 ml maximum).

The extracorporeal circulation system consisted of a soft-shell venous reservoir, roller pump, membrane oxygenator (Univox, Baxter Healthcare Corp, Irvine, CA, USA), arterial line filter, cardiotomy reservoir and polyvinyl tubing system. All parts of the extracorporeal circuit were treated with surface-bounded heparin (Duraflo II, Baxter). In all cases, the extracorporeal circuit was primed with 1650 ml. The prime solution in the crystalloid group contained lactated Ringer's solution 1500 ml, 20% mannitol 100 ml, 8.4% sodium bicarbonate 50 ml and heparin 5000 IE. The prime solution in the colloid group contained MFG 1000 ml, lactated Ringer's solution 500 ml, 20% mannitol 100 ml, 8.4% sodium bicarbonate 50 ml and heparin 5000 IE. In this prime composition, COP is 32 mm Hg and oncotic pressures were expected to be in the normal range (20–25 mm Hg in whole blood) after mixture of the prime with the patient's blood.

To perform sub-total CPB, a standard cannulation technique was used with cannulae placed in the ascending aorta and in the right atrium (two-stage venous cannula). After systemic heparinization (300 IE kg^{-1}), CPB was commenced, provided that the activated clotting time was more than 400 s. The left ventricle was vented via the aortic root. Blood from the pericardial cavity was collected in a cardiotomy reservoir and returned to the patient. Packed cell volume (PCV) during CPB was maintained at 22–24%; if possible, autologous blood was taken from the patient via the venous cannula just before the onset of extracorporeal circulation. Non-pulsatile flow rate was maintained at 2.2–2.4 litre min^{-1} m^{-2} and patients were cooled to 29–30 °C nasopharyngeal temperature. Mean arterial pressure during CPB was maintained at 50–80 mm Hg and if pressure declined to less than 50 mm Hg, flow rate was increased and vasoactive drugs were given. After aortic cross-clamping, all patients received crystalloid cardioplegia for myocardial protection (800–1000 ml, potassium 16 mmol litre^{-1}, 4 °C). Distal anastomoses of the grafts were placed during aortic cross-clamping, while proximal anastomoses were constructed after aortic cross-clamp release and recommencement of mechanical ventilation. Acid–base balance was managed following the alpha-stat concept. Patients were weaned from CPB using inotropic support if necessary. After termination of CPB, heparin was neutralized using an equivalent dose of protamine sulphate 3 mg kg^{-1}. Autologous blood and residual volume from the extracorporeal circuit were infused as first-choice fluid administration. Guided by low filling pressures, MFG and 0.9% NaCl were infused additionally.

POSTOPERATIVE CARE

After operation, all patients were transported to the intensive care unit (ICU), where they were treated according to a standard regimen. Haemodynamic units were: heart rate 70–80 beat min^{-1}, mean arterial pressure 65–80 mm Hg, pulmonary artery wedge pressure 8–12 mm Hg and cardiac index > 2.5 litre min^{-1} m^{-2}. Inotropic support was guided by the individual status of the patient. Fluid balance, rectal temperature and peripheral temperatures were recorded every hour. The peripheral circulation was considered to be adequate if the difference between rectal temperature and peripheral skin temperature (ΔT, measured on the back of the foot) was less than 5 °C. Patients were ventilated to normocapnia and an arterial oxygen tension > 11 kPa with continuous positive pressure breathing, and positive end-expiratory pressure of 5 cm H_2O. Extubation was permitted if the following criteria were met: (i) an awake and co-operative patient with a spontaneous ventilatory frequency of 10–20 bpm, (ii) positive pressure support ⩽ 5 cm H_2O, (iii) arterial oxygen tension > 11 kPa and (iv) inspired oxygen fraction ⩽ 40%. The minimal required postoperative intubation time, that is the moment that all four criteria were fulfilled, was recorded, independent of the medical decision to extubate the trachea at that time. Basic i.v. fluid administration consisted of 0.9% NaCl. MFG 4% and 20% human albumin (CLB, Amsterdam, Netherlands) were infused if COP was less than 15 mm Hg. Red packed cells were transfused if PCV was less than 26%. Blood loss and blood requirements were recorded until 18 h after operation.

BLOOD SAMPLING AND INFLAMMATORY MEDIATORS

All blood samples are obtained from the radial artery catheter or the arterial site of the extracorporeal circulation circuit. PCV, leucocyte counts and platelet counts were determined at all sample moments. Concentrations are not corrected for dilution.

Colloid oncotic pressure

Blood (1 ml) anticoagulated with ethylenedinitrotetra-acetate was used to measure whole blood COP. Samples were taken at the following times: 5 min before the start of CPB, 5 min, 20 min and 45 min after the start of CPB, at the end of CPB, and 1, 4 and 18 h after operation.

Endotoxin

Under pyrogen-free conditions, blood 6 ml was collected in heparin-anticoagulated tubes (Monovette, Sarstedt, Nümbrecht, Germany) and immersed immediately in crushed ice. After preparation of platelet-rich plasma, samples were stored at −70 °C in polystyrene tubes (Falcon 2063, Oxnard, CA, USA). Endotoxin concentrations were estimated using an optimized assay based on lipopolysaccharide-dependent activation of limulus amoebocyte lysate (LAL) and subsequent chromogenic measurement of activated LAL (Coatest Endotoxin, Kabi-Chromogenix, Molndal, Sweden). The LAL material contained in this batch of Coatest endotoxin kits is insensitive to LAL-reactive material, for example β-glucan, and therefore produces specific endotoxin data [15, 16]. The endotoxin concentration is presented as endotoxin units per millilitre of platelet-rich plasma (EU ml^{-1}), with 0.012 u. of endotoxin corresponding to 1 pg of endotoxin. The assay has a laboratory detection limit of 0.036 EU ml^{-1} and a clinical lower decision limit for endotoxaemia of 0.06 EU ml^{-1}. Blood samples were obtained before induction of anaesthesia (baseline), 10 min after the start of CPB, after cessation of CPB, and 1 and 18 h after arrival in the ICU. A sample was also obtained from the prime solution of the extracorporeal circuit just before connecting it to the patient.

Complement activation

Blood (2 ml) was collected in tubes and anticoagulated with ethylenedinitrotetra-acetate and immersed immediately in crushed ice. After preparation of platelet-poor plasma, samples were stored at −70 °C. C3b/c (C3b, iC3b and C3c) was measured using anti-C3-9 as capture antibody, which binds to C3b/c and also iC3. C4b/c (C4b, iC4b and C4c) was measured using anti-C4-1 as capture antibody, which binds to C4b/c and its degradation products C4b, iC4b and C4c. Blood samples were obtained before induction of anaesthesia, 20 min after the start of CPB, at the end of CPB, 20 min after protamine infusion and 4 h after arrival in the ICU.

Tumour necrosis factor-α (TNFα) and neutrophil elastase

Blood (2 ml) was collected in tubes containing citrate and immersed immediately in crushed ice. After preparation of platelet-poor plasma, its volume was divided in half, placed in two separate tubes and stored at −70 °C. Concentrations of TNFα were determined using an immunoradiometric assay (TNFα IRMA, Medgenix, Brussels, Belgium), with a detection limit of 5 ng $litre^{-1}$. Concentrations of neutrophil elastase were determined using an activating immunization method (Merck Diagnostica, Darmstadt, Germany) with an automated homogenous enzyme immunoassay (Hitachi 717 selective analyzer, Boehringer, Mannheim, Germany). Blood samples were obtained before induction of anaesthesia, after cessation of CPB, and 1, 4 and 18 h after arrival in the ICU.

ENDPOINTS OF THE STUDY

Fluid balance was calculated separately during CPB, at the operating room and during the first 18 h after operation. Volume of administered fluids, urine output, blood loss in surgical sponges and suction traps, and mediastinal and chest tube drainage were recorded. Insensible fluid losses were assumed equal among the groups and therefore were not included in the fluid balance.

To estimate the inflammatory response to CPB, a score based on face validity was used. Face validity refers to qualitative attributes of a score or index that are appraised with judgements of experts involved in patient treatment [17, 18]. This "clinical performance score" is composed of the sum of (i) the total fluid balance until 18 h after operation (measured during surgery and every hour at the ICU), (ii) mean ΔT during the first 18 h in the ICU (measured every 2 h) and (iii) time of fulfilment of extubation criteria divided by 4. In this way, all components of the score have a comparable range and therefore a comparable weight in the score. A higher score indicates a more pronounced inflammatory response.

The number of days in the cardiac surgical unit (ICU included) from surgery until transfer to the referring cardiologist was recorded. Criteria for transfer were: fully co-operative and mobile patient, walking stairs, devoid of chest tubes, without extra oxygen without pulmonary oedema on chest x-ray, signs of infection or arrhythmia in the last 24 h.

DATA ANALYSIS

Data were stored and analysed using standard computer software (Statview 4.02, Abacus concepts, Berkeley, CA). Inter-group comparisons were assessed with *t* tests, Mann–Whitney *U* test and Fisher's exact test. To analyse changes within each group, one factor analysis of variance (ANOVA) for repeated measures was applied, supplemented with the Scheffé *post hoc* test. The distribution of biochemical data displayed considerable skewness and underwent log transformation before ANOVA was performed. Regression analysis was performed if appropriate. A two-tailed $P < 0.05$ was considered to be statistically significant. Values are presented as mean (SD), unless mentioned otherwise.

Results

Patient and surgical data in the study groups are shown in table 1. No complications occurred. All patients survived and all but one were discharged from the ICU on the first postoperative day.

In the crystalloid group, COP during CPB was lower compared with levels before and after CPB (fig. 1, $P < 0.01$). In the colloid group, COP remained virtually unchanged during the study. Significant differences in COP between groups occurred at all times during CPB. At the end of CPB, the decrease in COP compared with baseline (ΔCOP) was 8.5 (SD 1.5) mm Hg in the crystalloid group compared with 1.5 (2.9) mm Hg in the colloid group ($P = 0.0001$). There was a positive correlation between ΔCOP and fluid balance during bypass ($r^2 = 0.41$, $P = 0.002$). Patients in the crystalloid group required more additional fluid during CPB compared with patients in the colloid group (table 2). Fluid balance during CPB and during surgery was more positive in the crystalloid group. There were no inter-group differences in PCV, white blood cell count and platelet count, or in diuresis, blood loss and number of units of blood transfused. In the total study population, MFG 4.4 litre (range 2–6.5 litre) was administered per patient over 24 h. There were no correlations between units of MFG and blood loss ($r^2 = 0.03$) or between units of MFG and blood transfusion ($r^2 = 0.01$). Respiratory function, as measured by $P\text{O}_2/F\text{I}_{\text{O}_2}$ ratio, did not differ between groups (table 2).

Table 1 Patient characteristics and surgical data (mean (SD or range) or number). There were no significant differences between the groups. BSA = Body surface area, CPB = cardiopulmonary bypass time, LIMA = left internal mammary artery, LVEDP = left ventricular end-diastolic pressure

	Crystalloid prime	Colloid prime
Age (yr)	63 (63–75)	65 (65–73)
Sex (M/F)	9/1	9/1
BSA (m^2)	1.93 (0.15)	1.97 (0.19)
LVEDP (mm Hg)	15 (4)	15 (4)
Predonation (y/n)	6/4	7/3
CPB (min)	110 (31)	115 (42)
Anastomoses	4 (3–6)	4 (3–7)
LIMA (y/n)	7/3	5/5

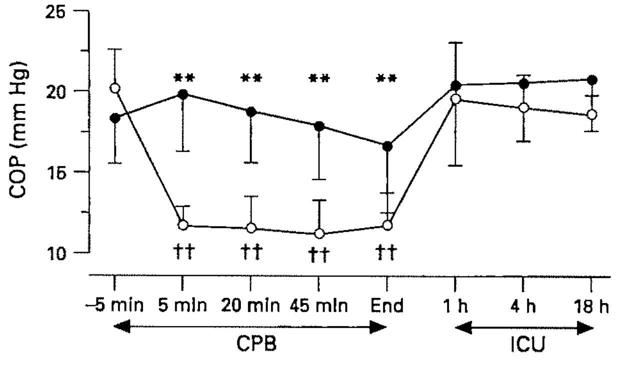

Figure 1 Colloid oncotic pressure (COP) during cardiopulmonary bypass (CPB) and in the intensive care unit (ICU) in patients treated with crystalloid prime (○) or colloid prime (●). $^{**}P < 0.01$ between groups; $^{\dagger\dagger}P < 0.01$ compared with baseline (–5 min CPB).

There were no differences in concentrations of inflammatory mediators between the groups (fig. 2). Throughout the study, endotoxin concentrations were near the limit of detection. C3b/c increased during CPB and after protamine infusion, followed by a decrease after 4 h in the ICU to levels that did not differ from baseline. C4b/c did not increase in each group during CPB or after protamine infusion. TNFα release exhibited a similar pattern in both groups, with increases during CPB and further increases to peak levels at 1 h in the ICU. Thereafter, TNFα concentrations decreased to levels that were not different from baseline. Positive correlations were found between TNFα at 4 h in the ICU and volume of fluid administration in the ICU ($r^2 = 0.32$, $P = 0.02$). Neutrophil elastase increased during CPB and levels after 18 h in the ICU were still higher compared with baseline.

There were no inter-group differences in mean arterial pressure, central venous pressure, pulmonary capillary wedge pressure, cardiac index (fig. 3), vascular resistance and vasoactive medication.

The clinical performance score and its components are depicted in table 3. A lower score was present in the colloid compared with the crystalloid group, whereas the individual components did not differ between groups. In each group, nine patients were transported to their referring hospital and one patient was discharged home (fig. 4). Median postoperative hospital stay for the referred patients was 7 (range 5–16) days in the crystalloid group and 5 (4–8) days in the colloid group ($P = 0.016$, Mann–Whitney test). A positive correlation was found between clinical performance score and postoperative hospital stay ($r^2 = 0.64$, $P = 0.0001$). To identify variables that influenced hospital stay, forward stepwise regression analysis was performed with the following independent variables: study category, sex, age, body surface area, duration of CPB and of aortic cross-clamping, ΔCOP, fluid balance, blood loss, mean ΔT, relative change in postoperative $P\text{O}_2/F\text{I}_{\text{O}_2}$ ratio and intubation time.

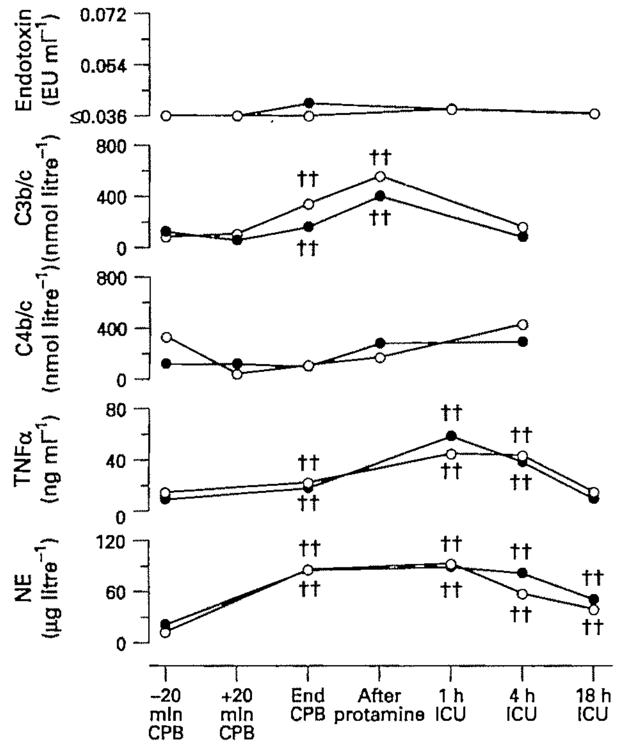

Figure 2 Median values of inflammatory mediators during cardiopulmonary bypass (CPB) and in the intensive care unit (ICU) in patients treated with crystalloid prime (○) or colloid prime (●). No significant differences were observed between groups. ††$P < 0.01$ compared with baseline (−5 min CPB). TNFα = Tumour necrosis factor-α, NE = neutrophil elastase.

The analysis yielded a regression model with three predictor variables: hospital stay = 2.37 + 0.01 × (CPB time) + 1.60 × (fluid balance at the end of the operation) − 3.28 × (Po_2/Fi_{O_2}), $r^2 = 0.87$, $P < 0.001$ (standard error of CPB time, 0.007, standard error of fluid balance, 0.18, standard error of Po_2/Fi_{O_2} ratio 0.002).

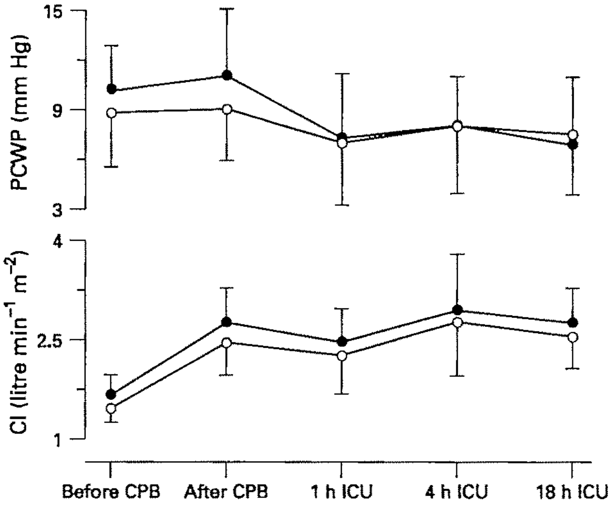

Figure 3 Pulmonary capillary wedge pressure (PCWP) and cardiac index (CI) before and after cardiopulmonary bypass (CPB) and in the intensive care unit (ICU) in patients treated with crystalloid prime (○) or colloid prime (●). No significant differences were observed between the groups. In both groups, CI after CPB and in the ICU was significantly higher compared with baseline.

Discussion

We have demonstrated that maintaining a normal COP during CPB can be established by adding MFG to the priming solution of a heparin-coated extracorporeal circuit with a small prime volume. The clinical benefits of a normal COP were reduced fluid administration, improved postoperative patient recovery and a shortened postoperative hospital stay.

Normal COP during CPB was achieved using a 2.4% MFG solution. This solution exerts a COP of 32 mm Hg, which is apparently sufficient to counteract the sudden haemodilution at the start of CPB and the cardioplegic solutions infused during aortic cross-clamping. The decline in COP at the onset of

Table 3 Clinical performance score = (i)+(ii)/4+(iii). Mean ΔT = Mean difference between rectal and peripheral skin temperature in the ICU, measured every 2 h until 18 h after operation. Values are mean (SD)

	Crystalloid prime	Colloid prime	P
(i) Fluid balance (litre)	5.6 (2.5)	3.8 (1.5)	ns
(ii) Extubation criteria (h)	21.9 (9.5)	18.7 (3.6)	ns

Clinical performance score	17.3 (4.8)	13.3 (2.4)	0.03

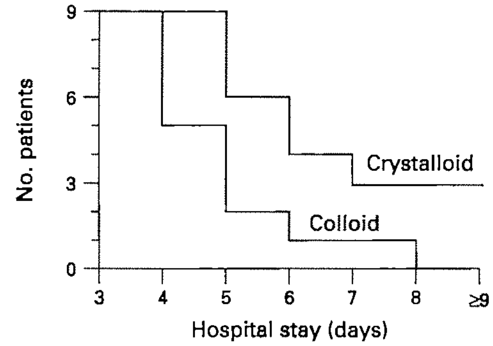

Figure 4 Patients treated with crystalloid prime had a longer postoperative hospital stay than those treated with colloid prime ($P < 0.02$).

CPB occurring with crystalloid primes induces fluid shifts across the capillaries [19]. To offset the low COP, extravascular stored albumin is transferred into the intravascular compartment in exchange for fluid shift towards the interstitial space [3]. Intravascular pressures are maintained within the normal range, but as observed in the crystalloid group, at the expense of a large amount of additional fluid administration during CPB.

The undetectable or low endotoxin concentrations found in this study may indicate that the intestinal microcirculation during and after cardiac surgery is not affected. Previously, we have reported endotoxaemia during CPB [20]. The initial vasoconstriction and duration of the low COP haemodilution were assigned as factors that determined the levels of endotoxin by the end of CPB. These findings prompted the clinical team to adjust the pre-CPB filling status of the patient, to modify the circuit by means of reduction in priming volume (from 2350 ml to 1650 ml) and to maintain an adequate arterial pressure during CPB. In this study with heparin-coated circuits, the inflammatory response was reduced. In these circumstances, COP maybe of secondary importance with regard to the intestinal microcirculation and endotoxin migration from the intestine into the circulation. In contrast, low COP during CPB, through its effects on fluid shifts, is likely to be a major contributory factor to intestinal ischaemia when capillary leakage occurs in association with an increased systemic inflammatory response.

The inhibitory effect of heparin coating on complement activation has been reported frequently [11–13]. As a sequel to reduced complement activation, there are decreased concentrations of neutrophil release products such as elastase, myeloperoxidase and lactoferrin [21]. In the present study, the pattern of complement activation was similar in both groups. Activation of the classic pathway, as represented by C4b/c, was not observed, either during CPB or after infusion of protamine [22]. Our findings emphasized that with the small prime volume heparin-coated circuits, in the absence of detectable endotoxins, activation of the alternative route of the complement cascade still occurred. The use of perfusion with normal COP apparently has no influence on activation of the complement cascade.

Sustained fluid administration was required in the postoperative phase in the crystalloid group and also in the colloid group, while no inter-group differences in COP or fluid balance were observed after operation. The reason for the rapid restoration of COP in the crystalloid group was probably that in both groups MFG was infused during sternal closure and in the ICU (table 2). In circumstances of profound haemodilution while on CPB, fluid administration is guided by sudden changes in COP. In the postoperative phase, when COP has returned to normal values, capillary leakage related to release of inflammatory mediators might determine the need for extra fluid infusion. This was confirmed by the, albeit weak, correlation between postoperative TNF concentrations and fluid administration during ICU stay. As shown in table 2, the contribution to the total fluid balance in both groups was higher during surgery than during ICU stay. The average stay in the operating room was approximately 4 h, while measurements in the ICU were spread over 18 h. The fluid shifts initiated by oncotic imbalance are likely to outweigh the contribution to interstitial fluid accumulation related to the inflammatory response.

In both groups, large amounts of MFG were administered. Few data are available on the efficacy of the recently available modified gelatins [23, 24]. In a prospective, randomized study, Himpe and colleagues reported the usefulness and safety of succinyl-linked gelatin as priming solution during coronary artery revascularization [25]. Our findings are in agreement with this study. Although we did not investigate the effects of MFG on blood clotting and haemostasis, we found no influence of MFG on postoperative blood loss and blood transfusion. The strong oncotic activity, relatively short effect (3–4 h), dose limitation solely by dilution and the low price of MFG in comparison with other artificial colloids suggest that it is suitable for short-term plasma substitution treatment.

So far, studies dealing with the contents of priming solutions have failed to provide significant clinical advantages for colloid priming compared with crystalloid priming [5–7], as the majority of patients tolerate CPB well, which makes it difficult to measure a clinical response. Furthermore, in our hospital, low-risk patients who underwent elective coronary artery surgery were usually discharged from the ICU the morning after operation, which was also the case for all but one patient in the present study. For that reason, ICU stay is not a useful marker of postoperative recovery. As an alternative approach to determining differences in postoperative clinical performance, we previously introduced the use of a score system based on face validity [18]. The score is composed of three variables of equal weight, all more or less related to the systemic inflammatory response to CPB. A favourable score was calculated in patients treated with colloid priming in comparison with those treated with crystalloid priming, while none of the components of the score differed significantly between groups. This indicates that, even after low-risk coronary artery surgery, the postoperative clinical recovery could be improved in patients treated with a normal COP perfusion. The predictive value of the score is denoted by the significant correlation that was calculated between the score and hospital stay.

Discharge from hospital occurred earlier in the colloid group. Patients had to fulfil criteria of mobility and independence before they were discharged to the referring cardiologist. As illustrated by the regression analysis, CPB time, fluid balance during operation and postoperative $P\text{O}_2/F\text{I}_{\text{O}_2}$ ratio were independent factors that predicted postoperative hospital stay. As normal COP perfusion resulted in a significantly decreased fluid balance, the impact of colloid prime on hospital stay was confirmed.

Pupil changes during cardiopulmonary bypass

G. C. FLETCHER, A. J. ASBURY AND J. H. BROWN

Summary

Pupil diameter is used during anaesthesia to assess depth of anaesthesia and indicate cerebral hypoxia. This is especially so during cardiac bypass when other autonomic signs cannot be monitored. We have used a pupillometer to determine the effect of cardiopulmonary bypass on the pupil. We have also investigated if any effect was caused by washout of opioid from the central nervous system by allocating patients to one of two groups: in one the bypass pump was preloaded with fentanyl, in the other with 0.9% saline. Cardiopulmonary bypass caused pupil dilatation of between 17% and 53%, which was unaffected by preloading the bypass pump with fentanyl. This effect lasted for the duration of the study, which ended 30 min after the start of cardiopulmonary bypass. Sympathetic nervous system reflexes and hypothermia may account for this observation, but further research is necessary to exclude other contributory factors. (*Br. J. Anaesth.* 1996; **76**: 20–22)

Key words

Heart, cardiopulmonary bypass. Equipment, pupillometer. Measurement techniques, pupil diameter.

Cardiac anaesthetists are likely to inspect the pupils at several stages during operation and especially during the bypass phase. Subjective assessment of pupil size has been used as one component to estimate depth of anaesthesia [1]. Increasing concern regarding postoperative morbidity is now evident [2, 3] and has focused attention on possible predictive factors, such as alterations in pupil diameter and reactivity [4].

There are few publications on the effect of cardiopulmonary bypass (CPB) on the eye. One of these has described a surprising increase in intraocular pressure (IOP) [5]. The pupillary response to the commencement of CPB has never been documented.

Many physiological and pharmacological factors affect pupil diameter [6, 7], including opioids, anticholinergics, ganglion blockers, sympathomimetics, histamine and steroids. However, the sudden change in so many variables which occurs on starting CPB makes speculation on the resulting pupillary changes unproductive.

A recently developed pupillometer [8] which is robust, easy to use and accurate (0.1 mm) now permits pupillary changes, perhaps previously undetected, to be observed. The aim of this study was twofold: first, to record pupil changes which occur when patients undergo CPB. It was postulated that any change in pupil diameter may be the result of a washout effect of the bypass prime solution on the opioid in the Edinger–Westphal nucleus. Therefore, our second aim was to determine if preloading the bypass pump with fentanyl affected the observed pupil changes.

Patients and methods

Local hospital Ethics Committee approval was obtained and informed consent was given by all participating patients.

Observations of pupil size were carried out in 20 patients, aged 44–69 yr. Eye colour was noted as this has been shown to affect pupil reactivity. Patients were premedicated with lorazepam 2–3 mg the night before and 2–3 mg on the morning of operation. The anaesthetic technique was similar in all patients. Anaesthesia was induced with fentanyl 5 μg kg^{-1} i.v. and propofol, delivered from a target-controlled infusion pump set to infuse to a target of 1–3 μg ml^{-1} [9]. All patients were given pancuronium 0.2 mg kg^{-1} and anaesthesia was maintained with an infusion of fentanyl of 10 μg kg^{-1} h^{-1} (to a total of 30 μg kg^{-1}) and a target-controlled propofol infusion [9]. The lungs were ventilated with an air–oxygen mix ($F\text{I}_{O_2}$ of 0.4). Arterial pressures and central venous pressures were monitored by invasive techniques. A further bolus of fentanyl 5 μg kg^{-1} was given just before incision.

In all cases the extracorporeal circulation involved a Cobe CMS, flat sheet membrane oxygenator primed with Hartmann's solution 2000 ml, heparin 8000 u., potassium chloride 15 mmol, sodium bicarbonate 50 mmol, mannitol 10 g and cefuroxime 750 mg. Patients were allocated randomly into one of two groups using opaque envelopes (saline or fentanyl). In group F, fentanyl 5 μg kg^{-1} was injected into the reservoir of the pump before bypass, in the NonF group, an equivalent volume of normal saline was given into the reservoir. The patients were unaware of the group into which they were placed as was the researcher who measured pupil diameter. The cardioplegic solution (St Thomas' solution 700–1000 ml) was given to cause asystole. During

bypass methoxamine i.v. was given to maintain mean arterial pressure greater than 40 mm Hg. At the surgeons' request, 16 patients were cooled to a temperature of 28 °C and four were cooled to 30 °C.

Pre-bypass pupil diameter was recorded during the last minutes before commencing CPB. Readings were then recorded at 30 s, and at 1, 3, 5, 10, 15, 20 and 30 min thereafter.

The Mann–Whitney *U* test in Minitab version 9.2 was used to assess statistical significance between the independent groups and the Wilcoxon signed rank sum test was used for intra-group comparison. Significance was taken at $P < 0.05$.

Results

There were 17 males and three females in the study. Of these patients, 18 were undergoing coronary artery bypass graft, one mitral valve repair and one aortic valve repair. None of the patients had an eye disease other than being long-sighted.

The ages of the patients in the two groups (F and NonF) were not significantly different ($P < 0.05$). Median age in group F was 59 (interquartile range 51.75–65.25) yr and in group NonF 59 (53.75–63.75) yr. Thirteen patients had blue eyes, three brown, two green and two grey. The time to commencement of CPB varied between 50 and 140 min.

There was a significant increase in pupil diameter ($P < 0.001$) compared with pre-bypass size at all times of measurement after the start of CPB (fig. 1). The time of maximum pupil dilatation was 5 min when median dilatation was 0.4 mm (interquartile range 0.3–0.5 mm). Maximum pupil size observed in any one patient was 0.9 mm and the minimum was 0.3 mm. The magnitude of the observed increase in pupil diameter during CPB was not significantly affected by preloading the bypass pump with fentanyl (fig. 2). The population size was too small to make inferences about the effect of eye colour, although the mean pre-bypass diameter and the mean maximum change in diameter for each eye colour is shown in table 1.

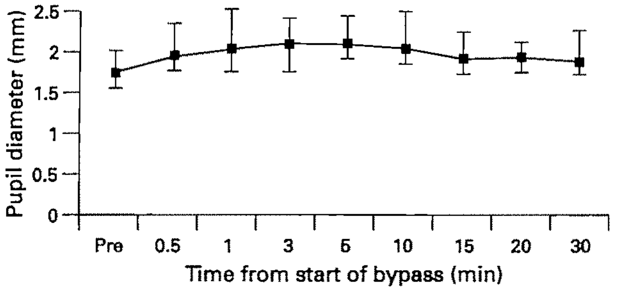

Figure 1 Median (interquartile range) pupil diameter before (Pre) and after commencement of cardiopulmonary bypass.

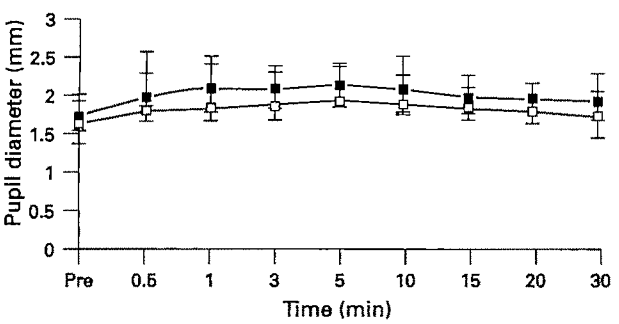

Figure 2 Median (interquartile range) pupil diameter before (Pre) and after commencement of cardiopulmonary bypass in patients whose bypass pump was preloaded with fentanyl (■) or 0.9 % saline (□).

Table 1 Effect of eye colour on the changes in pupil diameter during CPB

Eye colour	No. of patients	Mean pre-bypass pupil diameter (mm)	Mean maximum pupil dilatation (mm)
Blue	13	1.76	0.52
Green	2	1.35	0.45
Brown	3	1.73	0.43
Grey	2	2.05	0.4

One patient developed bilateral conjunctivitis after operation which was considered to be unlikely to be related to the study as only one eye was used for pupil measurements, and nothing came into contact with the surface of the eye.

Discussion

During general anaesthesia there are variations in pupil size [6, 7] and these changes tend to be more pronounced when autonomically active drugs, opioids and central nervous system depressants are given. Such effects occur throughout cardiac anaesthesia, but the sustained and reproducible pattern of pupil dilatation which we have observed during CPB is likely to depend on other physiological variables.

Patients in the study received moderate doses of fentanyl and the mean pre-bypass pupil diameter of 1.75 mm correlates with the effects of a bolus dose of fentanyl to an anaesthetized patient, when mean pupil diameter is reduced from approximately 3.0 to 2.0 mm [10]. Opioids are thought to affect the pupil by reducing cortical inhibition of the Edinger–Westphal nucleus. Binding of fentanyl to receptors in this area might be influenced by the sudden change in plasma concentration as the crystalloid prime flushes through the body. However, this is unlikely as the changes in pupil diameter in the group which had the bypass prime solution preloaded with fentanyl did not differ significantly from those in which the pump was preloaded with saline.

Hypothermia itself is known to dilate the pupils [11] and also reduce IOP. This factor may have played a part in causing the observed pupil dilatation. Investigation of patients undergoing normothermic CPB would help to clarify this.

Autonomic effects on the pupil, mediated via the ciliary ganglion, are obvious in conscious people, and in ophthalmic surgery direct effects of topical autonomically active drugs are used to good effect [12]. During CPB, it is likely that there is both a neurotransmitter and a neuroendocrine response caused by emptying of the atria of the heart and a tendency for a reduction in mean arterial pressure. Measurements of plasma catecholamine concentrations have shown that during CPB plasma noradrenaline concentration increases to a maximum at 60 min and dopamine concentrations increase by 500% at 15 min and then diminish over the next 45 min [13]. In this context it is worth noting the results of Von Sallmann and Lowenstein who used electrode stimulation of the ventral zone of the hypothalamus in cats to mimic the effects of diffuse sympathetic nervous system discharge [14]. They found that IOP increased, but did not comment on any effects on the pupil. It might be expected that a central sympathetic response to the sudden hypotension of CPB would produce much larger increases in pupil diameter than we have observed. Also, the corresponding increase in IOP described by Stellpflug and colleagues [5] was of only a moderate degree. An explanation may be that pupil reactivity is attenuated by the central opioid effect, and hypotension, while triggering the sympathetic nervous system to increase IOP, itself tends to lower IOP [15].

Although sympathetic activity provides a likely explanation for the observed increase in pupil diameter associated with CPB, other physiological variables may play a part [16–21]. There was also a source of error in this study as a result of reading the pupillometer.

Vecuronium infusion requirements in paediatric patients in intensive care units: the use of acceleromyography

U. M. HODGES

Summary

Neuromuscular blocking drugs in intensive care units (ICU) may cause complications, including prolonged neuromuscular block as a result of overdosage and post-ventilation muscle weakness. These may be increased by using inappropriately high infusion rates for infants, in whom published studies are scarce, and by failure to monitor neuromuscular block. There is little ICU experience of acceleromyography, which may permit more reliable monitoring. To determine appropriate vecuronium infusion rates, 12 neonates/infants (median age 4 (interquartile range (IQR) 2–5) months) and 18 children (median age 3.07 (2–10) yr) were studied. The vecuronium infusion rate was adjusted to maintain train-of-four (TOF) at 1 response using the TOFguard accelerometer. Recovery time was measured from cessation of infusion until spontaneous TOF ratio recovery of 0.7. Neonates and infants required 45% less vecuronium (mean infusion rate 54.7 (SEM 4.23) $\mu g\ kg^{-1}\ h^{-1}$) than older children (98.7 (7.07) $\mu g\ kg^{-1}\ h^{-1}$) and had faster recovery to 70% T4/T1 (45 (IQR 20–51) min *vs* 65 (55–103) min), with no evidence of prolonged weakness. Routine monitoring of neuromuscular block in ICU is essential; acceleromyography is convenient and reliable. (*Br. J. Anaesth.* 1996; **76**: 23–28)

Key words

Monitoring, neuromuscular function. Measurement techniques, acceleromyography. Neuromuscular block, vecuronium. Infants. Intensive care.

Neuromuscular blocking drugs facilitate tracheal intubation and mechanical ventilation. Indications for intensive care use include: maintenance of a motionless state in critically elevated intracranial pressure, tenuous surgical repairs or haemodynamic instability; reduction of oxygen consumption; severe rigidity; and to facilitate procedures [1–3]. However, significant problems are reported and there is little published research into the use of these drugs in paediatric ICU practice. The aim of this study was to determine appropriate vecuronium infusion rates in paediatric ICU and assess acceleromyography for monitoring neuromuscular block in the ICU.

Long-term use of neuromuscular blocking agents may be associated with prolonged weakness, either from prolonged neuromuscular block [4] or from a poorly characterized myopathy [1]. It occurs more commonly with aminosteroid blockers [2] but is found with benzylisoquinolinium compounds [3]. Neuromuscular block may be prolonged by drug overdose or by accumulation of active metabolites [5]. Risk factors for prolonged weakness include hypocalcaemia [6], renal failure [7, 8], metabolic acidosis and hypermagnesaemia [8]. Aminoglycosides prolong the action of neuromuscular blockers by inhibition of presynaptic acetylcholine release and stabilization of postjunctional membranes [9].

Alternatively, tachyphylaxis caused by spontaneous breakdown of atracurium or alterations in protein binding, receptor sites (up-regulation) or volume of distribution may occur. In up-regulation, extrajunctional cholinergic receptor proliferation significantly increases requirements for neuromuscular blockers over time [10]. Other complications of these drugs include histamine release [11] and cardiovascular instability. Atracurium, for example, can cause hypotension and tachycardia at higher doses or on rapid administration [12]. Laudanosine, an atracurium metabolite, may cause seizures in animals [5]. These drugs are also implicated in "ICU psychosis" if ICU staff believe muscular paralysis is a calm, painless state not requiring extra analgesia/sedation [13, 14].

One contributory factor in paediatric ICU may be lack of published research, so that inappropriately high infusion rates are used for infants, leading to overdosage, particularly when neuromuscular function is not monitored. The standard ICU regimen for vecuronium is a bolus of 0.1 $\mu g\ kg^{-1}$, followed by 60–600 $\mu g\ kg^{-1}\ h^{-1}$ [15], but during anaesthesia, neonates and infants need 40% lower infusion rates than older children [16].

Neuromuscular function is rarely well monitored in the ICU [17, 18], thus increasing neuromuscular blocking drug and metabolite accumulation and resulting in reports of prolonged neuromuscular block [19, 20] and, it is suggested, myopathy by "overkilling" the receptors [19]. Monitoring is essential because the critically ill ICU patient has altered pharmacodynamics and pharmacokinetics for

CP25787

drugs, metabolic disturbances and possible drug interactions, making it impossible to predict the dose of neuromuscular blocker required. Judging train-of-four (TOF) response manually (or visually) with certainty is difficult [19, 21] and electromyography and mechanomyography are too cumbersome for routine ICU use. Acceleromyography (with the TOFguard) may be the answer but experience with this technique in the ICU is scarce [19].

The purpose of this study was to determine if neonates/infants require lower infusion rates than older children and to assess the TOFguard accelerometer for paediatric ICU use.

Patients and methods

The study was approved by the Hospital Ethics Committee and informed consent was obtained from the parents of each child. Thirty critically ill patients who were expected to require neuromuscular blocking drugs to assist controlled ventilation were allocated to the study. Sedation was provided throughout by continuous infusion of morphine, midazolam, or both. Routine monitoring of the patients was in accordance with the practice of the unit and included electrocardiogram, direct arterial pressure and temperature measurement (core and peripheral). Arterial blood-gas and electrolyte measurements were carried out twice a day or more often if required, and adjustments made to ventilation and acid–base balance as necessary. The intensive care clinicians used their neuromuscular blocking drug of choice for intubation. The drug given and the dose were recorded.

Neuromuscular function was monitored at the ulnar or tibial nerve using the TOFguard nerve stimulator (Organon Teknika, Cambridge). This makes use of the Newtonian principle that acceleration is proportional to force. The piezoelectric ceramic wafer produces an electrical signal proportional to acceleration. The TOFguard is a compact, microprocessor-controlled, solid state, battery-powered system. It can deliver TOF measurements (supramaximal stimulation TOF 2 Hz), post-tetanic count and, during the recovery phase, TOF ratio. It can be programmed for use in the intensive care unit to monitor long-term relaxation and delivers a TOF stimulation every 5 min. The data are stored and can be played back from a memory card.

After tracheal intubation, neuromuscular block was monitored until the first TOF response (TOF 1) returned, at which time an infusion of vecuronium was started (with a concentration of 0.2–2 mg ml^{-1}), using a Wellmed syringe driver pump. Guidelines for the initial vecuronium infusion rate were as follows: $<$ 1 yr 20–40 μg kg^{-1} h^{-1}; 1–10 yr 100 μg kg^{-1} h^{-1}; $>$ 10 yr 70 μg kg^{-1} h^{-1}. The TOF guard was programmed to deliver a supramaximal TOF stimulus every 5 min. The aim was to maintain TOF at one response. The infusion rate and TOF response were reviewed hourly and if there was no response to TOF stimulation or three or more responses were present, the infusion was reduced or increased by 10% of the original rate until one response was present. If the rate was changed then the TOF response was reviewed at 5–15-min intervals until stable at TOF 1 response. After initial demonstration by the author, the infusions were administered and controlled by the nursing staff. To determine the dose of vecuronium required for each patient and if it altered over time, a manual record was kept hourly of the vecuronium infusion rate, the cumulative dose infused, the TOF response and any other drugs given concurrently. Alterations to the infusion rate were also recorded. In addition, to determine if the time to spontaneous recovery was affected by the age of the patient, duration of infusion or other factors such as renal failure, the time from cessation of infusion to spontaneous recovery of a TOF ratio of 0.7 was recorded.

STATISTICAL ANALYSIS

Two sample Student's *t* test was used for parametric data (infusion rates) and Mann–Whitney *U* test for non-parametric data (recovery times) together with regression analysis of recovery times (Minitab PC version release 8) [22].

Results

Thirty patients were studied. The range of clinical conditions included pneumonia (six patients), asthma (one), head injury (nine), smoke inhalation (one), bronchiolitis (one), laryngotracheitis (one) and postoperative cardiac surgery (11). There were 12 patients aged less than 1 yr (median 4 (interquartile range (IQR) 2–5) months) and 18 children aged over 1 yr (3.07 (2–10) yr). The duration of infusions varied between 6–187 h (median 64.5 (IQR 30–81.5) h. Recovery times were available for 10 infants and 17 children (one neonate died during the study, one was transferred to another hospital and one infusion was discontinued after 6 h without the recovery time being recorded). Four patients developed renal failure requiring peritoneal dialysis during the study.

There was an age-dependent statistically significant difference in vecuronium requirements. The mean infusion rate for those less than 1 yr was 54.7 (SEM 4.23) μg kg^{-1} h^{-1}, while for children over 1 yr it was 98.7 (7.07) μg kg^{-1} h^{-1} with 95% confidence interval (CI) of 24.8–63; the *t* test statistic was 4.7, with 28 degrees of freedom (df) and an associated *P* value of 0.0001 (table 1).

There was also an age-dependent statistically significant difference in recovery times between the

3	2.03	TOF	126.5	22	55
4	0.03	ALCA	30.7	187	Died

Table 3 Mean (SEM) duration of "short" and "long" infusions, together with patient details. There was no significant difference between median (IQR) age or weight, mean (SEM) infusion rate or median (IQR) recovery time for the two groups

	"Short" infusions	"Long" infusions
Duration (h)	26.64	94.75
	(3.76)	(9.76)
Age (yr)	1.5	1.5
	(0.04–4)	(0.04–5)
Weight (kg)	11.95	11.8
	(5.32–18.25)	(4.99–24.85)
Infusion rate (µg kg^{-1} h^{-1})	79.9	82.2
	(8.56)	(8.71)
Recovery time (min)	55	60
	(24–64)	(47–100)

two groups. The median recovery time was 45 (20–51) min in neonates/infants and 65 (55–103) min in older children, with 95% CI of 10–60 and an associated P value of 0.0019 (table 1).

Two infants and two older children required peritoneal dialysis for renal failure (table 2). While the infusion rate for infants was lower than the sample mean, there was no apparent difference in infusion requirements for older children. None of the patients with renal failure demonstrated prolongation of recovery from the sample median. On re-analysing the data for vecuronium infusion requirements, without the four patients in renal failure, there was still an age-dependent statistically significant difference ($P = 0.0007$).

The regression equation for recovery times for all patients overall against duration of infusion was: recovery = 35.7 + 0.456 duration, with R^2(adj) = 20.9% and $P = 0.006$. This might suggest that time to spontaneous recovery of a TOF ratio > 0.7 is related to the duration of infusion. However, the equation is highly influenced by the only outlier. This patient became very active shortly after the infusion of vecuronium was discontinued. When a child is very active it is difficult to obtain a TOFguard reading, even when obvious clinical signs of recovery, such as sustained headlift, are being demonstrated. Until nursing stimulation ceased and there was adequate sedation, there was no accurate TOF result. The recovery time finally obtained therefore reflected the time to finishing nursing activities rather than spontaneous recovery. If the analysis is repeated without this value, the equation becomes: recovery = 44.8 + 0.292 duration, with R^2(adj) = 4.9% and $P = 0.148$, that is there would appear to be no significant relationship between the duration of infusion and recovery time. There was no evidence of prolonged weakness in any of the patients or of drugs such as aminoglycosides or steroids influencing the time to recovery.

This study also found no evidence of an overall reduction in vecuronium requirements over time to suggest cumulation, or of an increase in requirements which might indicate tachyphylaxis. A regression analysis comparing duration of all infusions against infusion requirements showed no significant relationship. In addition, if the mean infusion rate for the first 6 h of the infusions (79.21 (SEM

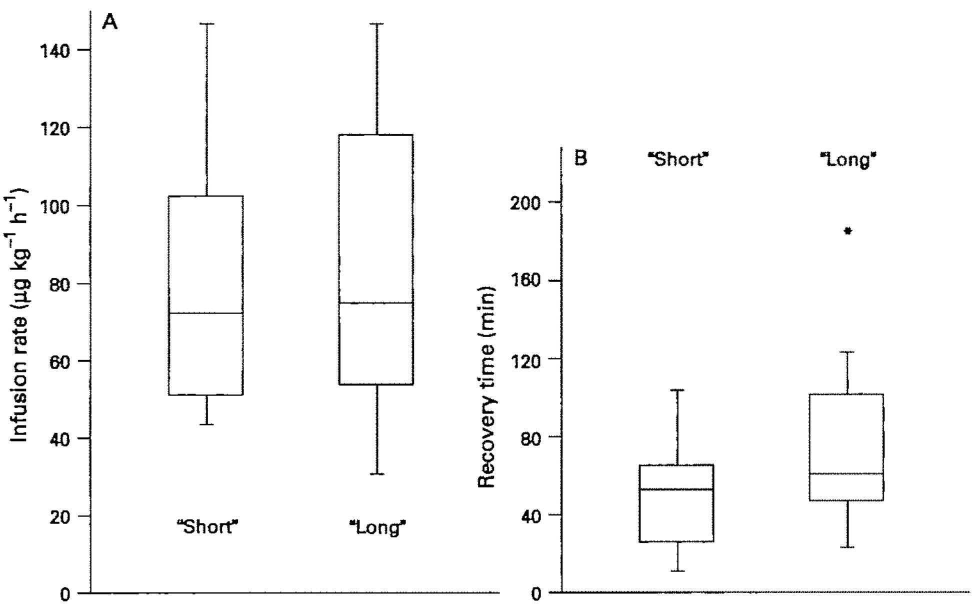

Figure 1 A: Percentile box plot of vecuronium infusion rates for "short" and "long" infusions. B: Percentile box plot of recovery times for short and long infusions. The box shows the difference between the quantiles; the median is indicated as a line and the whiskers show the extremes. The asterisk shows a possible outlier [22]. There was no significant difference in either dosage or recovery times.

6.62) $\mu g\ kg^{-1}\ h^{-1}$) is compared with that for the final 6 h of the infusions (87.86 (7.11) $\mu g\ kg^{-1}\ h^{-1}$), there is no significant difference. For the two age groups the mean infusion rate for patients less than 1 yr was 55.82 (7.38) $\mu g\ kg^{-1}\ h^{-1}$ for the first 6 h compared with 55.36 (3.76) $\mu g\ kg^{-1}\ h^{-1}$ for the final 6 h (ns), while for those over 1 yr, the mean infusion rate was 94.35 (7.97) $\mu g\ kg^{-1}\ h^{-1}$ for the first 6 h compared with 108.88 (8.04) $\mu g\ kg^{-1}\ h^{-1}$ for the final 6 h (ns).

In addition, previous research has mainly analysed data from infusions lasting less than 48 h. In this study there were 14 patients who received infusions for less than 48 h ("short" infusions); these results may be compared with data from the 16 patients who received infusions for longer than 48 h ("long" infusions) (table 3). There was no difference in age or weight between these two groups. Also, there was no significant difference in infusion rates between the two groups (fig. 1A). Recovery times varied between 15 and 105 min in the short infusion group and between 22 and 180 min in the long infusion group (fig. 1B) (ns). The data were re-analysed removing any outliers because of the variation in recovery times seen in both groups. Despite this re-analysis without the 105-min recovery time in the short group and without the 22-min recovery time in the long group, there was still no significant difference between them.

Discussion

In this study there was an age-dependent statistically significant difference in vecuronium requirements in the paediatric ICU. Neonates and infants required 45% less vecuronium than older children.

The neuromuscular effects of bolus doses of vecuronium have been studied previously [23–27], demonstrating an age-dependence of dose and recovery times [23, 26]. Similarly, infusion requirements during fentanyl–nitrous oxide–oxygen anaesthesia have been found to be 40% lower for neonates/infants (62 (SD 15) $\mu g\ kg^{-1}\ h^{-1}$) than for children aged 3–10 yr (154 (49) $\mu g\ kg^{-1}\ h^{-1}$) [16]. The ED_{95} of vecuronium for all patients less than 1 yr, including neonates, is 47 $\mu g\ kg^{-1}$ and is the product of the distribution volume and its plasma concentration [26]. Neuromuscular blocking drugs are distributed to the extracellular fluid volume which is approximately 44% of body weight at birth; only approaching the adult value of 22% at 1 yr of age [28]. In neonates and infants, therefore, it is concluded that during anaesthesia, neuromuscular block is reached at a lower total plasma concentration of vecuronium than in older children. The lower serum protein concentrations in neonates/infants may also indicate that lower total plasma concentrations of neuromuscular blocking drugs are needed.

There are few studies on vecuronium infusions in paediatric ICU and none comparing neonates/infants with children. An infusion rate of 66 (37) $\mu g\ kg^{-1}\ h^{-1}$ is reported but in only 12 patients (mean age 35.5 months (range 3 weeks to 13.5 yr)), with no attempt to analyse by age and with infusions of only 12 h in duration [29]. Another report of four neonates, three infants and eight children unfortunately combined the results for infants and children (mean dose of 140 (SD 0.05) $\mu g\ kg^{-1}\ h^{-1}$) to compare them with neonates (110 (0.05) $\mu g\ kg^{-1}\ h^{-1}$) [17], thus making comparison with studies during anaesthesia difficult. It suggested that the infusion rates were higher than those during anaesthesia because patients required a longer period of lung ventilation. It may be argued, however, that they reflect, instead, the relatively small sample size; that is, given the wide inter-individual variation in requirements seen in the present study (30.7–147 $\mu g\ kg^{-1}\ h^{-1}$), their smaller numbers reflect the higher end of the range, rather than being a true population sample. Also, only three infusions lasted longer than 48 h, unlike the present study where 16 of 30 infusions lasted longer than 48 h. The present study confirms the findings from short infusions and bolus usage of age-dependence in the vecuronium dose–response curve.

In addition, the present study showed an age-dependent difference in recovery times between neonates/infants and older children, with faster recovery in the former. Others, however, have found an age-dependent prolongation of spontaneous recovery in neonates and infants, arguing that this results from their greater distribution volume [30]. This study is widely quoted to show that vecuronium has a longer duration of action in neonates/infants than in older children. Why then is the opposite the case in this present study? The age-dependent prolongation of spontaneous recovery quoted refers to the time to full restoration of TOF 1 response. When TOF 1 response is restored, they also found that TOF ratio recovered faster in younger patients, suggesting proportionally more rapid restoration of muscle strength [30]. This age-dependence of TOF recovery has not been studied widely.

Another question addressed by this study was whether or not spontaneous recovery is affected by factors such as renal failure, as previously suggested [8, 31–33]. The four patients requiring peritoneal dialysis for renal failure did not have prolonged recovery but rather, in infants at least, needed smaller doses. Unlike previous reports, this study set out to adjust the infusion rate to maintain TOF at 1 response, as a fixed-dose infusion regimen in the presence of renal failure has been shown to lead to gradually increasing block [31]. Another study of seven patients with renal failure found prolonged neuromuscular block, lasting from 6 h to more than 7 days after termination of vecuronium [8]. However, neuromuscular function in these patients was monitored after the vecuronium infusion was discontinued. Those patients who, despite being in renal failure, did not develop prolonged block had received significantly smaller daily doses of vecuronium (median 0.29 (range 0.23–0.42) $mg\ kg^{-1}$) than those who did (0.65 (0.48–2.29) $mg\ kg^{-1}$) ($P < 0.05$). Other studies have shown that patients with chronic renal failure have increased sensitivity to the neuromuscular blocking effects of vecuronium [33]. Initially, the increased sensitivity is offset by the increase in distribution volume so induction doses should be equal to or slightly higher than for patients without renal failure. However, because of the increased sensitivity and a possible decrease in clearance, the maintenance doses need to be reduced. This study tends to confirm these findings.

It has been suggested that with time, tolerance and up-regulation of acetylcholine (ACh) receptors occurs in ICU patients receiving neuromuscular blocking drugs, leading to increased requirements [34]. Other factors leading to up-regulation include upper and lower motor neurone lesions, muscle trauma, burns, immobilization, anticonvulsants and clostridial toxins [35]. On the other hand, it is also proposed that prolonged recovery may occur with decreased infusion rates over time if accumulation of neuromuscular blocking drug or active metabolites occurs [36]. In this study duration of infusion did not appear to affect either the dose required or time to spontaneous recovery; that is, there was no apparent evidence of cumulation or ACh receptor up-regulation, provided infusions were titrated to individual patients. Longer infusions (8–12 weeks) may affect receptors differently [10].

Another potential problem is the development of a poorly characterized myopathy after long infusions, leading to weakness. This was not seen in the present study, despite the presence of factors such as renal failure which are thought to increase its incidence. This may result from the routine use of the nerve stimulator, which made it possible to achieve precise individual dosage of drug, avoiding "overkilling" of the ACh receptor [19, 20].

In conclusion, this study has shown that there is an age-dependent statistically significant difference in vecuronium requirements in the paediatric ICU. Maintaining the correct infusion rate revealed that neonates/infants have a faster spontaneous recovery from TOF 1 response to TOF ratio > 0.7 than older children. We also showed that renal failure does not prolong recovery when patients are fully monitored, with infusion rates adjusted to maintain TOF 1 response, but suggest that requirements may need to be reduced. Acceleromyography was a convenient and reliable method for monitoring neuromuscular function in the paediatric ICU.

Pharmacokinetics of rocuronium after bolus and continuous infusion during halothane anaesthesia

E. P. McCoy, R. K. Mirakhur, V. R. Maddineni, J. M. K. H. Wierda and J. H. Proost

Summary

We have studied the pharmacokinetics of a single bolus of rocuronium (Org 9426), followed by an infusion, in eight patients during anaesthesia with halothane and nitrous oxide in oxygen. Neuromuscular block was monitored using train-of-four (TOF) stimulation and recording the force of contraction of the adductor pollicis muscle. Rocuronium was administered as an initial bolus dose of 0.45 mg kg^{-1} followed by an infusion adjusted manually to maintain T1 (first response in the TOF) at 10% of control. Mean onset time and time to recovery of T1 to 10% were 72 (SD 19.6) s and 27 (9.6) min, respectively. The infusion rates were stable in 19.8 (6.5) min. The mean requirement for rocuronium for steady state 90% block of T1 was 528 (163.3) µg kg^{-1} h^{-1}. After cessation of surgery the infusion was stopped and patients were allowed to recover spontaneously. The times to attain a T1 of 90% and a TOF ratio of 0.7 were 31 (11.7) min and 36 (7.3) min, respectively. Blood samples were collected for 390 min after cessation of infusion and concentrations of rocuronium and its putative metabolites measured using HPLC. A two-exponential equation was used to describe the pharmacokinetic data. The rate of clearance, mean residence time and volume of distribution at steady state were 3.3 (0.77) ml kg^{-1} min^{-1}, 67.2 (18.8) min and 212.5 (40.1) ml kg^{-1}, respectively. The distribution ($T_{\frac{1}{2}}^{\alpha}$) and elimination ($T_{\frac{1}{2}}^{\beta}$) half-lives were 7.5 (3.33) min and 85.6 (18.4) min, respectively. These values were not significantly different from previously published data for a single bolus dose of rocuronium. (*Br. J. Anaesth.* 1996; **76**: 29–33)

Key words

Neuromuscular block, rocuronium. Pharmacodynamics. Pharmacokinetics, rocuronium. Anaesthetics volatile, halothane.

Rocuronium is a new monoquaternary aminosteroidal non-depolarizing neuromuscular blocking drug with an intermediate duration of action similar to that of vecuronium but with a much faster onset of effect [1–4]. Blockers with an intermediate duration of action, such as vecuronium and atracurium, have previously been shown to be suitable for administration by continuous infusion [5, 6]. Because of its rapid onset and intermediate duration of action, rocuronium has also been found to be suitable for use by continuous infusion [7, 8]. Previous pharmacokinetic studies after single bolus doses have shown the clearance and elimination half-life of rocuronium to be 2.5–3.97 ml kg^{-1} min^{-1} and 104–131 min, respectively [2, 9]. Blockers used over longer periods by infusion may show a progressive decrease in the drug infusion rate because of accumulation of drug in the distribution compartments [10, 11]. In the present study we have therefore estimated the pharmacokinetics of rocuronium when administered as a bolus followed by continuous infusion. The results were compared with previously published data for a single bolus dose [9].

Patients and methods

After obtaining informed consent and approval of the Regional Ethics Committee, we studied eight adult patients, aged 18–65 yr, ASA I and II, undergoing elective surgery lasting more than 1 h. These patients were part of a larger study assessing the use of rocuronium by continuous infusion. None had a renal or hepatic dysfunction or was receiving any medication known to interact with neuromuscular blocking agents. Any patient above 35 % or below 20 % of their ideal body weight was excluded.

After premedication with oral temazepam 10–20 mg, anaesthesia was induced with fentanyl 2–3 µg kg^{-1} and thiopentone 3–5 mg kg^{-1}, and maintained with 66 % nitrous oxide and 0.5 % halothane (inspired) in oxygen and additional doses of fentanyl. Heart rate (from ECG), non-invasive arterial pressure, end-tidal carbon dioxide concentration, oxygen saturation and temperature were monitored routinely. Ventilation was adjusted to maintain end-tidal carbon dioxide concentration at 4.5–5.5 %. Skin temperature over the adductor pollicis muscle was maintained above 32 °C.

The ulnar nerve was stimulated percutaneously at the wrist with supramaximal stimuli of 0.2 ms duration, in a train-of-four (TOF) mode at 2 Hz every 12 s; the resultant force of contraction of the adductor pollicis muscle was measured and recorded using a force displacement transducer and a neuromuscular function analyser (Myograph 2000, Biometer, Denmark Ltd). After stabilization of control responses over approximately 10 min, patients were given rocuronium 0.45 mg kg^{-1} as a single fast i.v. bolus. The time from the end of injection of the neuromuscular blocker to maximum block (onset time) was measured. Tracheal intubation was carried out when maximum block was present.

An infusion of rocuronium was commenced after recovery of the first response in the TOF (T1) to 10 % of control and its rate adjusted to maintain T1 at 10 %. The initial rate was about 15 μg kg^{-1} min^{-1} (900 μg kg^{-1} h^{-1}). The infusion rate and intensity of block were recorded every 10 min. At the end of surgery the infusion was stopped and the block allowed to recover spontaneously. The times for spontaneous recovery of T1 to 25 %, 75 % and 90 % of control and of the TOF ratio to 0.7 were recorded. Anaesthesia was stopped and the trachea extubated when appropriate.

Venous blood samples (4 ml) were obtained from a dedicated cannula before administration of rocuronium, at 1, 3, 5, 10, 15 and 30 min after administration of the bolus dose, at 5, 10 and 20 min after commencement of the infusion of rocuronium, and at 20-min intervals thereafter, and 1, 3, 5, 10, 15, 30, 60, 90, 150, 210, 270, 330 and 390 min after the infusion was stopped. Samples were also obtained at recovery of T1 to 25 % and when the TOF ratio was 0.7. Samples were collected in lithium heparinized tubes and centrifuged within 4 h. The plasma was acidified with sodium dihydrogen phosphate solution 1 mol $litre^{-1}$ (0.2 ml to every 1.0 ml of plasma) and stored at −18 °C until analysis. Analysis of rocuronium and its putative metabolites, 17-desacetyl rocuronium and 16-*N*-desallyl rocuronium was carried out using high pressure liquid chromatography (HPLC), with 3,17-didesacetyl vecuronium (Org 7402) as the internal standard [12]. The precision (reproducibility) of the method was 8 % over the range 10–100000 ng ml^{-1} for rocuronium, 7 % over 10–25000 ng ml^{-1} for 17-desacetyl rocuronium and 12 % over 10–25000 ng ml^{-1} for desallyl rocuronium. The lower limits of detection were 3, 5 and 15 ng ml^{-1} for rocuronium, 17-desacetyl rocuronium and desallyl rocuronium, respectively.

The plasma concentration–time data were analysed using the program Multifit (JH Proost, University Centre for Pharmacy, Groningen, The Netherlands). It uses standard procedures and pharmacokinetic formulae derived from the literature [13]. The method has been used previously both for single doses and continuous infusions of blockers [2, 9, 14]. Concentration *vs* time data were fitted for each patient to both a two- and three-exponential equation using Marquardt as the minimizing algorithm [15]. The choice between the two- and three-exponential equations was based on the *F* test [16]. The volume of the central compartment (V_c), steady-state distribution volume (V^{ss}), plasma clearance (*Cl*), elimination half-life ($T_{\frac{1}{2}}^{\beta}$) and mean residence time (MRT) were calculated using standard equations. Elimination was assumed to take place from the central compartment and MRT refers to the bolus dose.

The results were compared using a Mann–Whitney test with previously published data obtained after administration of a single bolus dose of rocuronium [9].

Results

Mean age, weight and height of the eight patients (seven male, one female) were 35 (range 18–59) yr, 67 (SD 8.4) (54–80) kg and 167 (4.9) (158–175) cm, respectively.

PHARMACODYNAMIC EFFECTS

Onset time (time from the end of injection to maximum effect) was 72 (SD 19.6) s and all patients attained complete block. The time to recovery of T1 to 10 % was 27 (9.6) min.

The mean rates of infusion required to maintain T1 at 10 %, recorded every 10 min, are given in table 1. There were large individual variations, as demonstrated by the large SD values. The rate was initially high but stabilized at 450–600 μg kg^{-1} h^{-1} in a mean time of 19.8 (6.5) min. The infusion rate showed a reduction from 70 min onwards but there were only two patients in the study beyond this time. The mean infusion rate for all patients over the entire period was 528 (163) μg kg^{-1} h^{-1}. The mean duration of the infusions was 74 (45.1) min (range 40–176 min) and the mean total dose of rocuronium administered was 1.0 (0.18) (0.66–1.18) mg kg^{-1}.

The speed of recovery after the infusions were stopped is shown in table 2. Mean times for recovery of T1 to 25 %, 75 % and 90 % of control were 9.1 (6.3), 26.0 (10.2) and 31.4 (11.7) min, respectively. Recovery index was 17 (6.2) min and the time to recovery of the TOF ratio to 0.7, 36.4 (7.3) min.

PHARMACOKINETICS

Figures 1 and 2 show the plasma concentrations of rocuronium in individual patients and the average for the group during the bolus dose and infusion maintenance, and in the post-infusion period. The plasma concentration decay was fitted (using the whole data set) to a simpler two- rather than a three-exponential equation as there was no significant difference between the two (mean coefficients of variance of 22 % and 17 % for the two- and three-exponential fits, respectively).

The kinetic characteristics are given in table 3. Mean V^{ss}, *Cl*, $T_{\frac{1}{2}}^{\beta}$ and MRT were 212.5 ml kg^{-1}, 3.3 ml kg^{-1} min^{-1}, 85.6 min and 67.2 min, respectively. The values were not significantly different from those obtained previously using a single dose of rocuronium [9]. No metabolites were detected in the plasma of any patient.

Table 1 Rocuronium infusion data (mean (SD) [range])

Time (min)	Infusion rate ($\mu g\ kg^{-1}\ h^{-1}$)	Twitch height (% of control)	No. of patients
0	888 (7) [800–1000]	10 (0) [10–10]	8

Discussion

The present study has confirmed that rocuronium is a neuromuscular blocking drug with a rapid onset of action, thought to be a result of its low potency, and is in keeping with other reports of its rapid onset of effect [1, 3, 4, 17]. This is obviously an advantage for rapid control of the level of block when the drug is used by infusion and this has been shown in the present and previous studies [7, 8]. Administration of neuromuscular blocking drugs by continuous infusion provides for greater stability of drug concentrations, and ensures greater consistency in the degree of paralysis [18]. When appropriately titrated to individual patient requirements, infusion techniques have the potential to avoid periods of both inadequate and excessive drug effects [10].

The times to recovery of neuromuscular function were not unduly prolonged after the infusions. The mean recovery index of 17 min after stopping the infusion was slightly less than that reported after single bolus doses of rocuronium. This may have resulted from the fact that the patients in the present study were recovering from a level of block of 90%

maintained by infusion rather than from a complete block using a bolus dose. In the latter situation more drug is redistributed during recovery from the peripheral to the central compartment, which then tends to slow the plasma concentration decay by distribution and elimination during the recovery phase [11].

Controlled infusions titrated to effect, minimize the transfer of drug to compartments other than the effect compartment. Use of blockers in this manner, therefore, results in a faster recovery than that resulting after a similar period of block using incremental maintenance doses. However, recovery may be prolonged, with an increased recovery index, after prolonged infusions because of saturation of the distribution compartments. In this situation, distribution of the blocker from plasma to the peripheral compartments contributes progressively less and less to reduction in plasma concentrations [11]. This was not the case in the present study where the duration of infusions was relatively short.

In the present study, no metabolites were detected in plasma in any patient. Metabolites in plasma or urine in humans have been found to be either absent or below the level of detection after 0.6 or 1.0 mg kg^{-1} bolus dose administration [2, 9].

Cooper and colleagues reported values of 207 ml kg^{-1}, 3.7 ml kg^{-1} min^{-1} and 97.2 min, respectively, for steady state volume of distribution, rate of clearance and elimination half-life with 0.6 mg kg^{-1} in patients with normal renal function during isoflurane anaesthesia [9]. Values using a dose of 1 mg kg^{-1} were reported as 270 ml kg^{-1}, 4.0 ml kg^{-1} min^{-1} and 131 min, respectively [2]. In the present study, mean steady state volume of distribution and elimination half-life were 212 ml kg^{-1} and 85.6 min, respectively, after a bolus dose followed by infusion. These variables are similar to those reported by Cooper and collegues in normal patients after a bolus dose of 0.6 mg kg^{-1}, although lower than those reported by Szenohradszky and colleagues who were studying patients undergoing renal transplantation [9, 19]. The rate of clearance was also similar to that reported in the previous study of single bolus dose administration [9]. Rocuronium concentrations were 1287 ng ml^{-1} at 25% recovery of T1 and had decreased to 711 ng ml^{-1} on recovery of the TOF ratio to 0.7, which were similar to those after single bolus doses of 0.6–1.0 mg kg^{-1} [2, 9].

The use of venous samples in the present study was based on convention. Although data obtained from arterial sampling may yield different and more accurate values, in particular for V_1, in the present study we used venous sampling to allow comparison with the results obtained from the previous single dose study based on venous sampling [9].

Although patients in the present study were anaesthetized with halothane compared with isoflurane in the study of Cooper and colleagues [9] with which the results from the present study have been compared, it has been shown that there are no significant differences in the kinetics of rocuronium during anaesthesia with these two agents [20].

Studies in the cat showed that less than 10% of rocuronium was excreted in urine and, as with vecuronium, most was excreted in bile [21]. However, previous work in healthy patients and those with renal failure has suggested a considerable role for renal clearance, with approximately 30% of rocuronium being recovered unchanged from urine [2, 9]. This was associated with greater interindividual variability of effect in patients with renal disease and the possibility of a longer duration of action of rocuronium in such patients [9]. It is likely that a similar trend will be observed after the use of rocuronium by infusion.

In conclusion, the present study indicates that rocuronium is suitable for infusions of moderate duration in patients with normal hepatic and renal function, with little difference in recovery and kinetic characteristics compared with single bolus doses. The absence of detectable metabolites is in keeping with previous work with single bolus dose administration and indicates minimal metabolism even with a total dose of 1.0 mg kg^{-1}. These results, however, do not preclude possible prolonged recovery with alteration in the kinetics of the drug after a much longer period of administration or in patients with significant renal or hepatic dysfunction, or both.

Acknowledgements

Supplies of rocuronium and financial assistance were received from Organon Teknika NV, Belgium. Rocuronium assays were carried out in the Department of Experimental Pharmacology at the University of Groningen.

Effect of suxamethonium on the auditory evoked response in humans

M. D. BRUNNER, D. NATHWANI, P. A. RICH, C. THORNTON, C. J. DORÉ AND D. E. F. NEWTON

Summary

We have studied the arousal effect of suxamethonium on the auditory evoked response (AER) of the electroencephalogram (EEG) in 40 ASA I and II patients during isoflurane anaesthesia. After induction of anaesthesia, the patient's lungs were ventilated for 20 min with 0.6 MAC end-expiratory isoflurane (0.59–0.77% depending on the age of the patient), and 50% nitrous oxide in oxygen. The patients were then allocated randomly to one of two groups: 21 received suxamethonium 1 mg kg^{-1}, while 19 were given saline. The AER before and after administration of suxamethonium or saline was compared to determine the changes in Pa and Nb amplitudes and latencies. Pa amplitude after suxamethonium increased by 53% (95% confidence interval (CI) 15,104%) compared with a reduction in Pa amplitude in the saline group of 19% (95% CI, −41,12%) ($P = 0.004$) suggesting an arousal effect. Similarly, Nb amplitude increased in the suxamethonium group by 47% (95% CI, 3, 110%) and decreased in the saline group by 11% (95% CI, −33,19%) ($P = 0.03$). We conclude that suxamethonium caused arousal according to the AER and postulate that this may have been caused by increased muscle afferent activity after stimulation of muscle spindles, although further studies are required to confirm this. (*Br. J. Anaesth.* 1996; **76**: 34–37)

Key words
Neuromuscular block, suxamethonium. Brain, evoked potentials. Monitoring, evoked potentials.

The auditory evoked response (AER) has been shown to reflect levels of anaesthesia [1]. The Pa and Nb waves are early cortical components of the AER which originate in the primary auditory cortex in response to an auditory stimulus. The early cortical responses show graded changes with increasing anaesthetic concentrations for a wide range of anaesthetic drugs [2–5]. In particular, the amplitude of Pa decreases and the latency of Nb increases with increasing depth of anaesthesia, while Pa amplitude increases and Nb latency decreases during emergence from anaesthesia. When a stimulus is applied to a patient during steady state anaesthesia, for example skin incision [6] or tracheal intubation [7], Pa and Nb amplitudes increase, suggesting arousal, although no significant change has been demonstrated in Nb latency. The AER therefore reflects both level of anaesthesia and the balance between anaesthesia and stimulation. During the course of other studies in which suxamethonium was used, we observed that suxamethonium caused an arousal effect on the AER. We therefore designed a study to investigate the effects of suxamethonium on the AER.

Patients and methods

This study was approved by the Harrow Research Ethics Committee. We studied 40 ASA I and II unpremedicated patients, aged 18–65 yr. All patients gave written informed consent. Patients were excluded if they were pregnant or if ventilation of their lungs using a laryngeal mask airway (LMA) was contraindicated (hiatus hernia, oesophageal reflux).

Anaesthesia was induced with propofol 1–2 mg kg^{-1} and an LMA was inserted. The patients' lungs were ventilated with a Manley MP3 ventilator to normocapnia, measured by a Datex Capnomac Ultima. Anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen. The end-expiratory isoflurane concentration was measured using a calibrated Datex Capnomac Ultima and was kept at 0.6 MAC, age-adjusted [8] (0.59–0.77% depending on the age of the patient), for 20 min to allow alveolar and brain concentrations of isoflurane to reach equilibrium [9]. Patients were then allocated randomly to receive either suxamethonium 1 mg kg^{-1} or saline control.

The AER was recorded from mastoid to forehead silver–silver chloride electrodes in response to a rarefaction click stimulus at 6 s^{-1}. This auditory stimulus was delivered to each ear simultaneously through close fitting ear pieces at 75 dB above the average hearing threshold. The EEG signal was analogue filtered on input with bandwidths of 25–

500 Hz to produce the AER recording which was displayed and stored continuously throughout the study on a portable computer. The AER recording continued for 2 min and 40 s after suxamethonium or saline to allow collection of 1024 sweeps of AER data. During this period, patients were left unstimulated to allow any change in AER to reflect the effect of suxamethonium or saline alone.

After each study the average of 1024 sweeps, representing 2 min and 40 s of AER data, before and after administration of suxamethonium or saline were filtered further using a high pass filter of 25 Hz and three-point smoothing. The waveforms were then printed out and analysed. Pa and Nb amplitudes and latencies were determined, and values before and after suxamethonium or saline were compared. The difference between values before (baseline) and after drug administration were calculated to show the effect of suxamethonium and saline on these AER variables.

For statistical analysis, all AER values were $\log_{10}$ transformed in order to produce homogeneity of variance and normality of residuals. A two sample *t* test was used to compare the mean change from baseline in the two groups. The difference between two logarithms is the logarithm of their ratios. When converted back to the original scale of measurement, a 95% confidence interval for the change from baseline on the logarithmic scale corresponds to a 95% confidence interval for the percentage change from baseline. The SD in the two groups for latencies were significantly different, and therefore a *t* test which does not assume equal variance was used for these values. The 95% confidence intervals for the geometric means of each group were also determined.

Results

We enrolled 44 patients into the study. Muscle artefact appears on the AER waveform in both unparalysed patients and during fasciculation in patients who have received suxamethonium. Data were included only when the underlying AER waveforms were unambiguously identifiable. On this basis data from four patients, two from each group, were excluded. Thus the results of 40 patients are presented (mean age 35.5 (range 18–63) yr; 22 females and 18 males). Twenty-one patients received suxamethonium and 19 were given saline as a control.

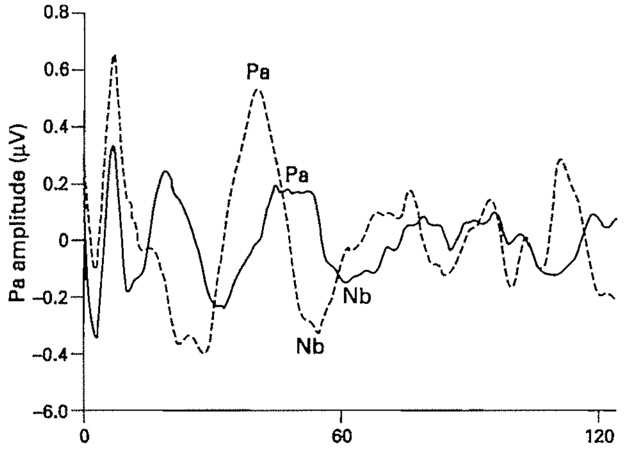

Figure 1 The auditory evoked response waveforms after an auditory click stimulus in a patient before (——) and after (——) suxamethonium. Changes in Pa and Nb amplitudes after administration of suxamethonium are illustrated.

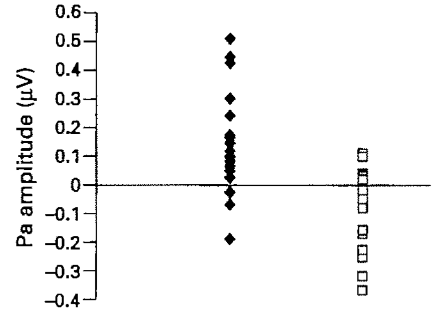

Figure 2 Change in Pa amplitude in patients after suxamethonium (◆) or saline (☐).

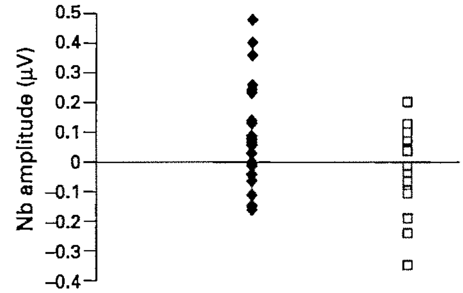

Figure 3 Change in Nb amplitude in patients after suxamethonium (◆) or saline (☐).

Typical changes in the AER waveform after suxamethonium were an increase in Pa and Nb amplitudes (fig. 1). Pa amplitude increased in 18 of 21 patients after suxamethonium and in only nine of 19 patients after saline (fig. 2). Similarly, Nb amplitude increased in 14 of 21 patients who received suxamethonium compared with eight of 19 in the saline group (fig. 3).

The percentage changes in Pa and Nb amplitudes and Pa and Nb latencies for both groups after suxamethonium or saline are shown in table 1. The mean percentage increase in Pa amplitude from baseline in the suxamethonium group was 53% (95% confidence interval (CI) 15, 104%) while in the saline group it decreased by 19% (CI −41, 12%) ($P = 0.004$) (fig. 4). Nb amplitude also increased significantly after suxamethonium compared with saline control. There were no significant differences for either Pa or Nb latencies between the two groups.

Discussion

The aim of this study was to assess the effects of suxamethonium on the AER during steady state isoflurane anaesthesia. We have shown that suxamethonium caused a significant increase in Pa and Nb amplitudes of the AER, similar to those after other stimuli, for example surgical stimulation and tracheal intubation [6, 7]. We conclude, therefore, that according to the AER suxamethonium caused arousal.

Table 1 Mean (95% confidence intervals) percentage changes in Pa and Nb amplitudes and Pa and Nb latencies from their geometric means in patients after administration of suxamethonium (Sux) ($n = 21$) or saline ($n = 19$). *P* values relate to the comparison of the percentage change from baseline in patients receiving suxamethonium or saline

AER variable	Treatment	Baseline geometric mean	% Change from baseline	*P*
Pa amplitude (μV)	Sux	0.19 (0.15, 0.23)	53 (15, 104)	0.004
	Saline	0.24 (0.17, 0.33)	−19 (−41, 12)	
Nb amplitude (μV)	Sux	0.19 (0.14, 0.26)	47 (3, 110)	0.03
	Saline	0.23 (0.18, 0.30)	−11 (−33, 19)	
Pa latency (ms)	Sux	42.4 (39.8, 45.2)	−12 (−16, −7)	0.05
	Saline	42.3 (38.9, 45.9)	−9 (−17, 1)	
Nb latency (ms)	Sux	60.8 (57.1, 64.9)	−14 (−19, −8)	0.5
	Saline	62.6 (58.7, 66.7)	−10 (−19, 1)	

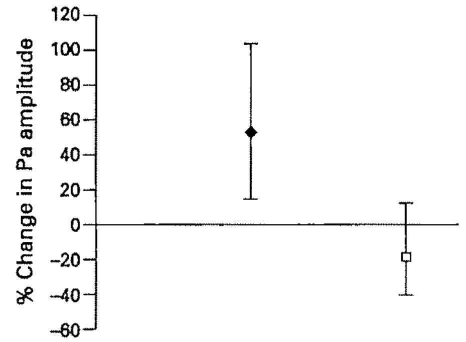

Figure 4 Mean (95% confidence intervals) percentage change from baseline in Pa amplitude for patients receiving suxamethonium (◆) or saline (□).

Previous studies have shown that suxamethonium produces an arousal pattern on the electroencephalogram (EEG) in anaesthetized humans. Mori, Iwabuchi and Fujita [10] demonstrated a change from 50–200-μV, 10–14-Hz spindle bursts to low voltage fast wave activity of 14–18 Hz. These changes occurred 60–90 s after administration of suxamethonium at a time when muscle fasciculation occurred. Oshima, Shingu and Mori [11] showed that activation of the EEG by suxamethonium was similar to that after surgical incision. This supports our findings that surgical incision and suxamethonium have similar arousal effects on the Pa and Nb amplitudes of the AER.

There are several possible causes for the arousal effects of suxamethonium. As this drug does not cross the blood–brain barrier [12] and has no effect on the EEG when injected directly into carotid arteries [13], its arousal effect on the EEG is thought to arise from its peripheral action. Muscle fasciculation caused by suxamethonium has been shown to cause arousal of the raw EEG in both humans [10, 11] and animals [13, 14]. Lanier, Milde and Michenfelder [14] showed that when dogs anaesthetized with halothane developed fasciculations after suxamethonium, there was an increase in electromyographic (EMG) activity leading to an increase in muscle spindle afferent activity, an arousal effect on the EEG and an increase in cerebral blood flow. All of these changes coincided with the duration of action of suxamethonium.

EEG arousal caused by suxamethonium, however, also occurs in the absence of fasciculation. In a later study by Lanier, Iaizzo and Milde [15], dogs anaesthetized with halothane were given a "defasciculating" dose of pancuronium (0.01 mg kg^{-1}) before administration of suxamethonium. Although this dose was insufficient to cause muscle paralysis to allow intubation, it did prevent fasciculation after suxamethonium. In these dogs, therefore, there was no change in EMG activity after suxamethonium. However, muscle spindle afferent activity increased, followed by EEG arousal and an increase in cerebral blood flow.

The arousal effect of suxamethonium on the EEG therefore, is not dependent on muscle fasciculation *per se*, but is caused by increased neuronal transmission to areas of the cortex which receive input from muscle spindles [16]. These are stimulated either indirectly as a result of extrafusal muscle fibre fasciculation, or directly by stimulation of muscle spindles themselves by suxamethonium. Suxamethonium has been shown to cause sustained contraction of intrafusal muscle fibres (muscle spindles) [17] resulting in increased muscle afferent activity [18]. This effect can be reproduced by repeated injections of suxamethonium [19] and blocked by complete neuromuscular block [20]. Indeed, a "paralysing" dose of non-depolarizing neuromuscular blocker before administration of suxamethonium has been shown to block EEG arousal after suxamethonium in humans [10] and dogs [14] anaesthetized with halothane. Increasing the depth of anaesthesia also obtunds the arousal effect of suxamethonium on the EEG [14], indicating the balance which exists between anaesthesia and stimulation. The mechanism by which suxamethonium causes arousal on the AER may be similar to that postulated for its arousal effects on the EEG. However, further studies on the effect of suxamethonium on the AER after pretreatment with a defasciculating or paralysing dose of a non-depolarizing neuromuscular blocker are needed to define the mechanism by which suxamethonium causes AER arousal.

Anecdotal evidence suggests that reports of awareness or arousal in anaesthetized patients are more common at, or around the time of tracheal intubation. This may be explained by the fact that two stimuli, administration of suxamethonium and tracheal intubation, both of which cause arousal according to the AER, occur almost simultaneously. The arousal effect of suxamethonium has been demonstrated in the clinical setting by Hobbs, Bush and Downham [21], in a study on paediatric patients anaesthetized with a nitrous oxide–oxygen–neuromuscular blocker technique. This study showed that the incidence of dreaming was increased ($P < 0.05$) if intermittent suxamethonium was chosen as the neuromuscular blocker (24%) compared with atracurium (9%). Minton and colleagues [22] showed, in a within-patient study, that intracranial pressure (ICP) in patients with brain tumours increased after suxamethonium, whereas this increase was blocked if suxamethonium was given after a paralysing dose of vecuronium. The authors concluded that the increase in ICP in their patients after suxamethonium alone resulted from an increase in cerebral blood flow produced by EEG arousal caused by stimulation of muscle spindles.

We postulate, therefore, that the increases in Pa and Nb amplitudes which we have described after suxamethonium, may result from cerebral arousal caused by increased muscle spindle afferent activity. The role of extrafusal muscle fasciculation in this phenomenon cannot be determined because our study was not designed to distinguish between the direct and indirect effects of suxamethonium on muscle spindles.

Analgesic effect in humans of subanaesthetic isoflurane concentrations evaluated by evoked potentials

D. ROTH, S. PETERSEN-FELIX, P. BAK, L. ARENDT-NIELSEN, M. FISCHER, P. BJERRING AND A. M. ZBINDEN

Summary

The aim of this study was to see if an analgesic effect of subanaesthetic concentrations of isoflurane could be detected with evoked potentials elicited by nociceptive stimuli. We studied 10 healthy volunteers breathing three steady-state subanaesthetic concentrations of isoflurane (0.08, 0.16 and 0.24 vol% end-tidal). Reaction time, subjective pain intensities and evoked vertex potentials to laser (LEP) and electrical (SEP) stimuli were recorded and compared with auditory evoked potentials (AEP). Compared with baseline, the subanaesthetic concentrations of isoflurane did not change the latencies of the evoked potentials, but caused a significant reduction in the amplitudes of the LEP and SEP at 0.16 and 0.24 vol% and of the AEP at all three concentrations. There were no changes in perceived pain intensity, and isoflurane produced similar reductions in evoked potentials elicited by both nociceptive and non-nociceptive stimuli. The reaction time was increased significantly at 0.24 vol% isoflurane. The results demonstrated that subanaesthetic isoflurane concentrations caused similar changes in evoked potentials with both painful and non-painful stimuli, with no effect on perceived pain intensity. (*Br. J. Anaesth.* 1996; **76**: 38–42)

Key words

Anaesthetics volatile, isoflurane. Pain, experimental. Monitoring, evoked potentials.

The analgesic effect of subanaesthetic concentrations of inhalation anaesthetics has been investigated by either clinical assessment [1–3] or pain threshold measurements [4, 5], but with conflicting results. In a recent study we found no analgesic effect of subanaesthetic concentrations of isoflurane on experimental pain tests [6]. These pain tests may, however, not always be able to detect a weak analgesic effect [7]. Laser stimulation may be a more sensitive method, as this has been used to demonstrate the analgesic effect of weak analgesics [8–11]. The purpose of the present study therefore was to see if evoked vertex potentials elicited by nociceptive electrical and laser stimulation could be used to detect weak analgesic effects of subanaesthetic concentrations of isoflurane.

Patients and methods

We studied 10 healthy volunteers (five male, mean age 24 (range 22–30) yr). They were not receiving any medication, had no allergies or adverse reactions to previous anaesthetics and, for the female volunteers, were not pregnant. Written informed consent was obtained and the study was approved by the Ethics Committee of the Faculty of Medicine, University of Bern.

To minimize the risk of acid aspiration, the volunteers received omeprazole 40 mg (Antra) the evening before testing, and were investigated after a fasting period of at least 6 h. During the tests the volunteers rested comfortably supine. An i.v. infusion of NaCl–glucose was given and Sp_{O_2}, ECG and non-invasive arterial pressure were monitored continuously. The subanaesthetic concentrations of isoflurane were delivered via a face mask. The breathing system and the gas monitors have been described previously [6].

The following tests were applied in a randomized order.

ARGON LASER STIMULATION

The output from an argon laser (Spectra Physics 168) was transmitted via a single 0.2-mm quartz fibre (output controlled with an external power meter). The distance to the skin was adjusted to obtain a laser beam diameter of 3 mm on the skin and a stimulus of 200 ms duration was applied to the dorsum of the right hand (C7 dermatome). The target area was divided into small sectors and, to avoid receptor fatigue, the sectors were stimulated sequentially. Pain threshold, defined as a distinct sharp pinprick, was determined with five ascending and five descending series of stimulation. For

recording of the laser evoked potentials (LEP), 16 laser stimuli with an intensity of 1.5 times the initial pain threshold and with a random inter-stimulus interval between 10 and 20 s were applied. After the last stimulation, the volunteer was asked to rate the perceived pain intensity on a visual analogue scale (VAS).

ELECTRICAL STIMULATION

An intracutaneous finger electrode applied to the pulp of the third finger was used [12]. A 25-ms single stimulus (in reality train of five, 1-ms, square-wave impulses, but these are perceived as a single stimulus) was delivered from a Digitimer DS 7 (Digitimer Ltd, Hertfordshire, England) constant current stimulator triggered by a Philips Generator PM 5150 (Philips GmbH, Hamburg, Germany). The current was increased from 0 in steps of 0.2 mA until the volunteer rated the perceived pain intensity of the stimulation on the VAS equally with that of laser stimulation. This intensity was then used for recording of the SEP. Application of the 16 stimuli and rating of perceived pain intensity were performed as for the LEP.

ACOUSTICAL STIMULATION

A binaural click with an intensity of 90 dB was provided by a Medelec ST 10 stimulator (Medelec Ltd, Surrey, England) through acoustically shielded headphones. For recording of the AEP, 16 stimuli with a random inter-stimulus interval between 10 and 20 s were applied as described for the laser and electrically evoked vertex potentials.

REACTION TIME

A tone was delivered from a computer with random intervals of 3–8 s, and simultaneously a timer was started. The volunteer was told to press a button as fast as possible after the tone. The reaction time was defined as the time from the tone until the volunteer pressed the button. The mean value of three consecutive measurements was used.

RECORDING OF THE EVOKED POTENTIALS

All evoked potentials were recorded from a needle electrode (Dantec, Denmark), inserted at Cz′ (according to the international 10–20 system) against a surface Ag–AgCl electrode on the right mastoid. The signal was filtered (bypass 0.1–30 Hz), amplified, recorded and averaged on a personal computer (PC) with the EPsys software (Aalborg University, Denmark) in the interval from 0.5 s before the stimulus until 2 s after the stimulus.

In order to familiarize the volunteer with the procedure, all experiments were explained before trial testing was performed. The mask was then fitted and the volunteer breathed air for 5 min, or until he felt comfortable, and there were no leaks from the mask. A baseline test series of the above described tests was then performed. Thereafter, isoflurane was introduced slowly into the breathing system and adjusted to the desired end-tidal concentration. This was chosen randomly from one of the three concentrations, 0.08, 0.16 and 0.24 vol%. We did not use concentrations higher than 0.24 vol% (about 0.2 MAC isoflurane), as volunteers at higher concentrations tend to be too sedated to co-operate [13]. After 15 min of equilibration at a constant end-tidal concentration, a test series was performed. This procedure was repeated with the two other isoflurane concentrations. The delivered isoflurane concentration was known only to the anaesthetist performing "anaesthesia". After testing had been performed at all three isoflurane concentrations, isoflurane was discontinued.

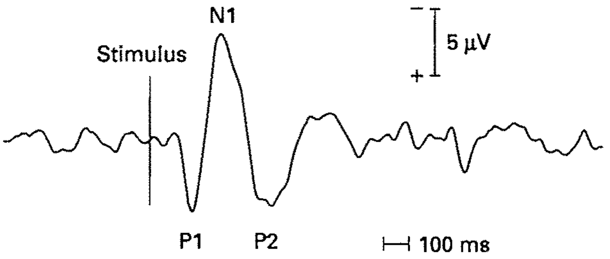

Figure 1 An LEP, which is the average of 16 evoked potentials elicited by short laser stimulations of 200 ms duration.

Latencies and peak-to-peak amplitudes of the first three major peaks, P1, N1 and P2 of the late LEP, SEP and AEP were measured (fig. 1). Statistical analysis was performed independently for each class of the evoked vertex potentials and the reaction time with the software SigmaStat v1.01 (Jandel Scientific GmbH, Erkrath, Germany). Median values and quartiles were calculated for the three isoflurane concentrations. The numerical values of all measurements were expressed as a percentage of baseline values. The values at the different isoflurane concentrations were compared with baseline using Friedman's test for repeated measures analysis of variance on ranks, and the Student–Newman–Keuls test for multiple comparison. $P < 0.05$ was considered statistically significant.

Results

Evoked vertex potentials were recorded in all subjects. There were no statistically significant changes in the latencies of the LEP and SEP compared with baseline (table 1) or with the AEP. The results in the peak-to-peak amplitudes are summarized in table 2. Statistically significant reductions compared with baseline were observed for P1–N1 amplitudes of the SEP at 0.16 and 0.24 vol% and for AEP at 0.08, 0.16 and 0.24 vol% isoflurane. N1–P2 amplitudes were reduced significantly for the LEP and SEP at 0.16 and 0.24 vol% and for AEP at 0.08, 0.16 and 0.24 vol% isoflurane. Furthermore, N1–P2 amplitude of the SEP at 0.08 vol% was reduced significantly less compared with those of the SEP and AEP at 0.16 and 0.24 vol%. There were no

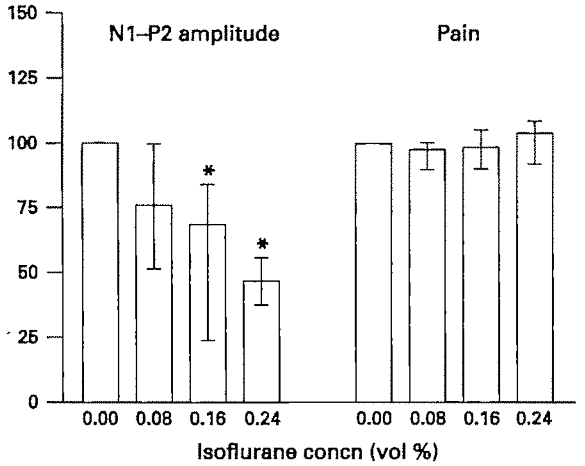

Figure 2 Argon laser stimulation. Comparison between the decrease in N1–P2 amplitude (expressed as percentage of baseline values) with increasing isoflurane concentrations of the long latency vertex potential to laser stimuli, and the perceived pain rated on a visual analogue scale. *Significantly different from baseline.

significant differences between the reductions in the amplitudes of the LEP and SEP compared with the AEP at each of the three isoflurane concentrations (figs 2–4).

There was no significant reduction in perceived pain intensity for either laser or electrical stimulation. Compared with baseline, median reaction time was 97.7% (25–75 percentiles 79.7–127.9%) at 0.08 vol%, 116.5% (94.2–128.7%) at 0.16 vol% and 161.1% (131.6–238.7%) at 0.24 vol%. Reaction time was increased significantly at 0.24 vol% compared with baseline, 0.08 and 0.16 vol%.

Discussion

We have shown that subanaesthetic concentrations of isoflurane did not change the latencies of the evoked vertex potentials, but caused a significant reduction in the amplitudes of the LEP and SEP at 0.16 and 0.24 vol% and of the AEP at all three concentrations. There was no change in perceived pain intensity, and isoflurane produced similar

reductions in amplitudes of the evoked potentials elicited by both nociceptive and non-nociceptive stimuli. The reaction time was increased significantly at 0.24 vol% isoflurane. We conclude that subanaesthetic concentrations of isoflurane have a sedative but no or only a minimal analgesic effect which the present techniques could not detect.

Several studies have shown that potentials, evoked by noxious laser stimuli, correlate with perceived pain intensity [10, 11, 14, 15]. In contrast, there is a lack of correlation between the amplitude of the vertex potential evoked by nociceptive electrical stimulation on the surface of the skin and subjective pain rating [16, 17]. This suggests that transcutaneous electrically evoked vertex potentials are not a reliable measure or correlate for changes within the nociceptive system.

In the present study electrical stimulation was applied using the intracutaneous technique [12]. This procedure ensured a high current density at the superficial nociceptors. As a consequence, pain thresholds were up to 10 times lower compared with transcutaneous stimulation. The sensation is described as a distinct pricking pain, very similar to that elicited by laser stimulation. This perception is attributed to the activity in the Aδ nociceptive afferents [18]. Kochs and colleagues [19] used the same technique for eliciting late SEP. They found that the recorded SEP were sensitive to opioid treatment during inhalation anaesthesia.

We did not find any correlation between the decrease in amplitudes of the LEP and SEP, and subjective pain rating. There was a reduction in the peak-to-peak amplitudes for the evoked vertex potentials elicited by nociceptive electrical and laser stimulation at the two higher isoflurane concentrations (see table 2), which could be interpreted as an analgesic effect [16, 20–22]. But the same decrease in the peak-to-peak amplitudes was observed also for the non-nociceptive AEP, and furthermore the perceived pain intensity did not differ significantly from baseline. These results suggest that the reduction in peak-to-peak amplitudes of the LEP and SEP are caused by a non-specific effect of isoflurane on the vertex potentials (sedation?) rather than by a specific analgesic effect on the nociceptive system.

We have shown that when evoked vertex potentials are used to investigate the analgesic effect of a drug, it is important not only to evaluate the effects of nociceptive stimuli, but also to control for a non-analgesic general effect on the evoked vertex potentials elicited by non-nociceptive stimuli. Furthermore, the electrophysiological responses should (when possible) be compared with subjective pain ratings. If we had measured only the effect of subanaesthetic concentrations of isoflurane on the amplitude of the evoked vertex potentials to painful laser and electrical stimulation, we would have presumed this to result from an analgesic effect, which in reality was not present.

Use of near infrared spectroscopy to estimate cerebral blood flow in conscious and anaesthetized adult subjects

H. OWEN-REECE, C. E. ELWELL, W. HARKNESS, J. GOLDSTONE, D. T. DELPY, J. S. WYATT AND M. SMITH

Summary

Near infrared spectroscopy (NIRS) can be used to quantify cerebral haemodynamic states non-invasively and to estimate cerebral blood flow (CBF). In the first part of this study we have compared CBF measurements in conscious and anaesthetized subjects. In the second part we have compared paired measurements made during anaesthesia, first on the scalp and then the dura after craniotomy. Mean CBF was 17 (SD 7) ml 100 g^{-1} min^{-1} in the conscious subjects compared with 21 (8) ml 100 g^{-1} min^{-1} on the scalp during anaesthesia ($P > 0.1$). Mean CBF on the dura was 68 (21) ml 100 g^{-1} min^{-1} ($P < 0.0001$). Computer modelling suggests that the difference in magnitude between scalp and dura measurements of CBF is likely to be caused by the optical effect of extracerebral tissue which powerfully scatters light passing through it but does not contribute significantly to the measured CBF because it has only a small blood content itself. The results lend support to this method of estimating CBF although formal validation by comparison with an established technique is needed. (*Br. J. Anaesth.* 1996; **76**: 43–48)

Key words

Brain, blood flow. Measurement techniques, near infrared spectroscopy.

Although the assessment of cerebral perfusion is of great clinical importance, the measurement techniques that are currently available have notable drawbacks. Some use ionizing radiation and others require cannulation of the large cerebral vessels. Doppler velocimetry is non-invasive but measures cerebral blood flow velocity and not cerebral blood flow (CBF) directly; furthermore, it is affected by changes in the diameter of the insonated vessel and the angle of insonation.

Near infrared spectroscopy (NIRS) is a non-invasive technique which is capable of measuring changes in the concentration of tissue oxy- and deoxyhaemoglobin (HbO_2 and Hb) [1, 2]. If optical fibre bundles are applied to the scalp, measurements can be obtained from the intact head. Several variables may be measured, including cerebral blood volume (CBV) [3], cerebral blood flow (CBF) [4] and the response of the cerebral circulation to alterations in Pa_{CO_2} [5]. The technique for measuring CBF was described initially using a bolus of HbO_2 generated in the lungs as a marker of brain-blood inflow but a modification using indocyanine green has been developed recently [6]. The HbO_2 method has been validated in newborn infants [7, 8]. The method has also been used to measure CBF [9] and forearm muscle blood flow in adults [10].

The aim of the first part of the study was to apply this technique using optical fibres placed on the scalp as described previously [9] in order to compare measurements of CBF in conscious adult volunteers with those made in patients undergoing general anaesthesia. The second part of the study, in patients undergoing craniotomy, compared measurements of CBF obtained when the optical fibres were placed on the scalp with measurements obtained using fibres placed directly on the dura.

Methods and materials

SUBJECTS

Conscious subjects

Eleven healthy volunteers with a mean age of 30 (range 21 to 44) yr gave informed consent. The subjects lay supine with eyes closed, breathing a gas mixture of oxygen and nitrogen from a modified anaesthetic machine using a mouthpiece and nose occluder. Fractional inspired oxygen concentration ($F_{I_{O_2}}$) (model 5550, Hudson, CA, USA), end-tidal carbon dioxide concentration (Datex Cardiocap, Datex Inc., Helsinki, Finland) or transcutaneous carbon dioxide concentration (Novametrix 850, Novametrix Inc., Wallingford, CT, USA), were monitored. Arterial oxygen saturation (Sp_{O_2}) was measured on the earlobe with a pulse oximeter

modified to update the value with every heartbeat (Nellcor N200E, Nellcor, Hayward, CA, USA). Heart rate was recorded from the pulse oximeter. The subject's haemoglobin concentration was estimated from a sample of blood.

Anaesthetized subjects

Ten anaesthetized patients were studied during neurosurgery for medically intractable epilepsy. Their mean age was 32 (range 19 to 48) yr. The neuropathological diagnosis in nine was hippocampal sclerosis. The remaining subject had a dysembryoplastic neuroepithelial tumour. The patients were otherwise healthy. Anaesthesia was induced with fentanyl 100 µg and thiopentone 3–6 mg kg^{-1} i.v. and maintained with isoflurane up to 1.1 % in 30–35 % oxygen with nitrous oxide. Vecuronium 0.1 mg kg^{-1} was used to provide neuromuscular block for tracheal intubation and paralysis was subsequently maintained with an infusion of the same drug. In addition to routine clinical monitoring end-tidal carbon dioxide and end-tidal isoflurane concentration (Datex Capnomac) were measured throughout the procedure. End-tidal isoflurane concentration was kept constant during CBF measurements. The lungs were ventilated to normocapnia. Mean arterial pressure (MAP) was measured either oscillometrically or by transduction from a radial arterial cannula. Incremental doses of fentanyl and labetalol were given to keep MAP as constant as possible throughout the studies. Sp_{O_2} was measured on the earlobe. Body temperature was not measured as all measurements were made close to the start of anaesthesia and normal warming techniques were employed. Near infrared spectroscopy measurements were obtained from the scalp in all 10 subjects and from the dura in seven subjects.

NEAR INFRARED SPECTROSCOPY (NIRS)

A portable NIRS apparatus (NIRO 500 or 1000, Hamamatsu Photonics KK, Hamamatsu, Japan) was used. Near infrared light at four (NIRO 500) or six (NIRO 1000) wavelengths between 700 and 910 nm was conveyed by a fibreoptic cable to the subject's head. A similar fibre bundle conveyed light transmitted through the head back to the apparatus. The end of the fibre (optode) was positioned on the left frontal region of the scalp avoiding the temporalis muscle. The median distance between the optodes was 4.2 (range 3.4–5.3) cm on the scalp. The optodes were covered with an opaque cloth to prevent interference from background illumination.

When measurements were made on the dura the optical fibres were sealed in sterile plastic film ('Steridrape', 3M) and held gently in position on the temporal dura using a Yasargil clamp (Down's Aesculap, London, UK). The interoptode distance was 2.5 cm.

Changes in light absorption were detected and converted into changes in the intracranial concentrations of HbO_2 and Hb using a previously established algorithm [11, 12]. This makes use of the Lambert-Beer relationship modified to take account of the increase in optical pathlength because of intense light scattering by biological tissue. A pathlength factor of 5.9 times the distance between the optical fibres was assumed [13]. Changes in total cerebral haemoglobin concentration (Hbsum) were calculated from the sum of the changes in HbO_2 and Hb concentrations. The details of these calculations have been described elsewhere [14].

Measurements were made continuously with a sampling interval of 0.5 s and displayed on a computer screen during the study. The NIRS, Sp_{O_2} and end-tidal carbon dioxide data were recorded simultaneously onto a computer disk for analysis later. All measurements were made under steady-state conditions.

The studies were approved both by the Joint Committee on the Ethics of Medical Investigation of University College London Hospitals and by the Joint Medical Ethics Committee of the National Hospital for Neurology and Neurosurgery and the Institute of Neurology. Informed written consent was obtained before each study.

CBF MEASUREMENTS

CBF was estimated using a modification of the Fick principle according to a previously established technique [4, 9]. A transient increase in Fi_{O_2} produced a bolus of HbO_2 which acted as an intravascular tracer; it was measured in the arterial system by pulse oximetry and its entry into the brain was detected by NIRS.

Before each measurement of CBF the Fi_{O_2} was reduced to allow Sp_{O_2} to equilibrate at 91–93 % for 10–20 s. Three to four breaths of 100 % oxygen were then given, causing Sp_{O_2} to increase rapidly to 97–98 % in less than 10 s. The change in cerebral HbO_2 concentration was determined by the NIRS apparatus. The first 4 s of tracer wash-in were taken for each estimation of CBF, on the basis of evidence that mean cerebral transit time is between 6 and 10 s [15]. After re-establishment of a stable baseline a mean of 4 usable measurements were obtained in each subject. The mean value for CBF was then calculated for each subject using the formula:

$$\mathrm{CBF} = \mathrm{K}\frac{\Delta \mathrm{HbO_2}}{\int_0^t \Delta f Sp_{O_2}\,dt}$$

where ΔHbO_2 is the change in haemoglobin concentration measured by NIRS in time t, $\Delta f Sp_{O_2}$ is the change in fractional arterial oxygen saturation and K is a constant incorporating blood haemoglobin concentration, molecular mass of haemoglobin and cerebral tissue density. This converts the units for CBF from µmol $litre^{-1}$ s^{-1} to ml 100 g^{-1} min^{-1}. As part of the CBF calculation procedure approximately 30 % of measurements are typically rejected on the basis of an excessively varying baseline Hbsum, end-tidal carbon dioxide or MAP. These aspects and others comprising the theoretical basis of the technique in adults have been discussed previously in detail [15].

STATISTICAL ANALYSIS

The values for CBF in conscious and anaesthetized subjects were compared using an unpaired *t* test. The values for CBF measured on the scalp and on the dura were compared with a paired *t* test.

Results

With the optical fibres positioned on the scalp, the mean CBF in the conscious subjects was 17 (SD 7) ml 100 g^{-1} min^{-1} compared with 21 (8) ml 100 g^{-1} min^{-1} in the anaesthetized subjects ($P > 0.1$). In the seven patients in whom CBF was measured on the dura, mean CBF with the fibres on the dura was 68 (21) ml 100 g^{-1} min^{-1} $P < 0.0001$ compared with the scalp. The values for CBF, heart rate and end-tidal carbon dioxide in the conscious volunteers are given in table 1. The values for mean end-tidal carbon dioxide and MAP in each anaesthetized subject are shown in table 2 together with the mean value for CBF in each subject. Table 3 shows the paired values for CBF measured on the scalp and dura during anaesthesia with the corresponding values for end-tidal carbon dioxide and MAP. Data collected during a typical

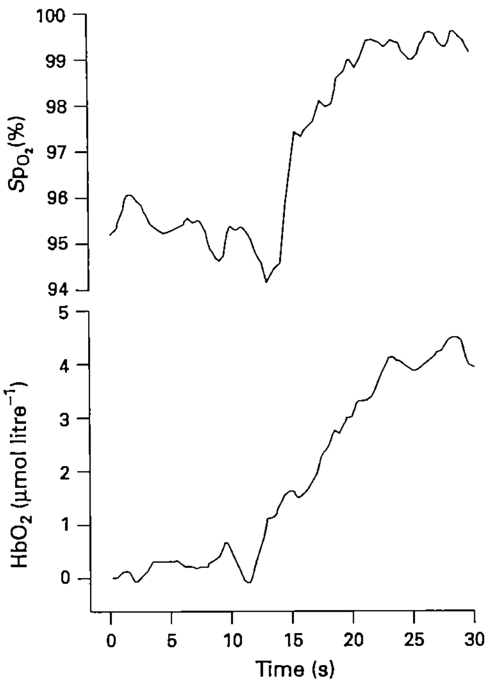

Figure 1 Representative data collected from an anaesthetized subject during a CBF measurement. The temporal offset between the increase in HbO_2 concentration and the increase in Sp_{O_2} is a result of the faster arrival of the tracer in the cerebral circulation than at the earlobe.

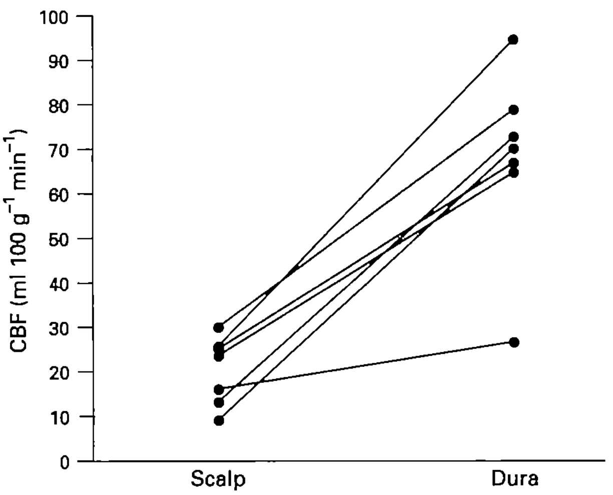

Figure 2 Cerebral blood flow (CBF) measured on the scalp and dura by NIRS in seven subjects.

CBF measurement are shown in figure 1 and the paired data for CBF on the scalp and dura are shown in figure 2.

Discussion

We have obtained non-invasive estimates of CBF using NIRS in adult subjects with the optodes placed on the scalp and directly on the dura. There are several assumptions underlying the use of NIRS to estimate CBF. In particular we have assumed that over the short period of the measurement (4 s) the small quantity of additional oxyhaemoglobin which enters the cerebral circulation acts as an inert tracer, and causes no significant effect on $CMRO_2$, CBF or cerebral blood volume (CBV). Previous physiological studies have shown that CBF is virtually constant when arterial oxygen tension varies between 5.7 and 12.3 kPa [16]. Furthermore, during our measurements the total cerebral haemoglobin concentration ([Hbsum]) was seen to remain constant, suggesting that, despite rapid changes in Sp_{O_2}, there had been no significant change in CBV. Finally, it is well known that, provided Sp_{O_2} is maintained within the physiological range, and brain metabolic requirements are being met, an increase in cerebral oxygen delivery does not result in an increase in oxygen extraction [17]. In these circumstances the small additional increment in HbO_2 concentration can be justifiably regarded as an inert tracer. This is discussed further elsewhere [9].

The values obtained for CBF when the optical fibres were positioned on the scalp were much lower than those obtained by invasive techniques, such as the i.v. ^{133}Xe washout technique [18], the Kety-Schmidt method [19], or by positron emission tomography (PET) [20]. However, the measured values for CBF when the optodes were positioned directly on the dura are in close agreement with those obtained using other established methods. Kety and Schmidt estimated mean CBF as 54 (12) ml 100 g^{-1} min^{-1} [21]. In healthy young men, a typical value by ^{133}Xe washout is 48 (7) ml 100 g^{-1} min^{-1} [18] and a typical value for grey matter by PET is 55 ml 100 g^{-1} min^{-1} [20].

The underestimation of CBF when the fibres were placed on the scalp is probably caused by the effects of extracerebral tissue on the transmission of light through the cranial cavity. Although it is a fundamental principle of NIRS that biological tissue is translucent to infrared light, nevertheless photons crossing the head travel on a path substantially longer than the linear distance between their points of entry and exit because of the scattering effect mentioned above. The true pathlength has been measured as 5.9 times greater than the linear pathlength (the interoptode spacing) in the adult head.

When this pathlength factor (DPF) is known, the distance that light has travelled through the head can be inserted into the Lambert-Beer equation and changes in haemoglobin concentration can be quantified. Computer modelling of near infrared light propagation in the adult head suggests that extracerebral tissue contributes 60–70 % of the total optical pathlength [22] but has very little blood flow (around 5–8 ml 100 g^{-1} min^{-1} [23]). When a rapid change in Sp_{O_2} is induced in order to make a measurement of CBF, the change in haemoglobin concentration occurs almost entirely in the cerebral tissue over the 4-s period of the measurement, since the blood flow to extracerebral tissue is so low. As cerebral tissue occupies only 30–40 % of the illuminated tissue volume the true CBF is thus underestimated by a factor which is equal to the ratio of the optical pathlength in brain compared with the total optical pathlength. When the optical fibres are placed directly on the dura the extracerebral component of the pathlength is reduced to zero and there is therefore no underestimation of CBF. Our results suggest that there is an approximately threefold underestimate of CBF with fibres on the scalp.

As the effects of extracerebral tissues are likely to be relatively consistent between different subjects, reliable comparisons of measurements between and within patients may be possible. In future it may be possible to determine directly the contribution of extracerebral tissue to the total optical pathlength in each subject, thus enabling CBF measurements obtained by NIRS from the scalp to be compared directly with measurements obtained by other techniques.

We did not observe a significant change in CBF as a result of anaesthesia in our study whereas there was a significant (approximately threefold) increase in CBF values measured on the dura in all except one patient. Mean arterial pressure was assumed to be in the normal range in the conscious objects and was not measured; the values for heart rate are normal supporting this assumption. The difference between end-tidal carbon dioxide, and Pa_{CO_2} is unlikely to have introduced a significant error. The mean end-tidal carbon dioxide of the anaesthetized group was the same as that of the conscious subjects (4.7 kPa). There was no significant difference in mean end-tidal carbon dioxide between measurements on the scalp and on the dura but it is notable that the patient with the smallest difference between scalp and dura CBF (patient 5) exhibited a decrease in end-tidal carbon dioxide and the patient with the greatest change (patient 3) exhibited an increase in end-tidal carbon dioxide. Two patients had arterial pressures which were close to the lower end of the autoregulatory range but in both cases the values for MAP on the scalp and dura were almost identical. The neuropathological diagnoses in the anaesthetized group were unlikely to have influenced CBF.

The drugs used during anaesthesia are thought to have minimal effects on CBF. In human studies to date, fentanyl [24] has not been observed to cause a significant increase in CBF, although in one study, when given at a dose of 10 μg kg^{-1} it caused a decrease [25]. Similarly, the administration of isoflurane is not associated with an increase in CBF when administered in nitrous oxide to a combined MAC of 1.5 [26, 27]. No patient in our study received an inspired isoflurane concentration greater than 1.1% in 60% nitrous oxide (i.e. a combined MAC of 1.7) and most received less. In each patient the end-tidal isoflurane concentration was maintained at a constant value for both sets of measurements.

The evidence on the effect of nitrous oxide on CBF is less clear although there is a tendency for CBF to increase during anaesthesia. In one recent study, CBF was measured by ^{133}Xe washout in volunteers during the inhalation of 30% and 50% nitrous oxide. CBF was said to be significantly greater breathing nitrous oxide than air although absolute values were not given [28]. In another study also using ^{133}Xe washout, patients receiving 35% oxygen in air or nitrous oxide, supplemented with isoflurane, nitrous oxide caused an increase in CBF from 40 to 57 ml 100 g^{-1} min^{-1} [29], a 43% rise. Our study showed an increase of 24% from 17 to 21 ml 100 g^{-1} min^{-1} but this was not statistically significant. In summary, we are not able to demonstrate a significant effect of general anaesthesia on CBF with the present technique.

We conclude that NIRS has the potential to provide non-invasive bedside assessment of CBF in adult subjects when the contribution of surface tissues to the differential pathlength factor in each individual studied is quantified. Although the values obtained from the scalp appear to underestimate the true CBF because of the optical effect of the extracerebral tissues, the technique allows comparison of measurements between and within subjects. In neurosurgical procedures involving craniotomy NIRS allows intraoperative measurement of CBF with the optical fibres positioned on the dura. The values thus obtained are in close agreement with those obtained by other means. Although further validation studies are required this technique appears to have potential for the non-invasive, bedside assessment of cerebral perfusion.

Effect of transdermal hyoscine on nausea and vomiting during and after middle ear surgery under local anaesthesia

P. HONKAVAARA

Summary

The efficacy of transdermal hyoscine in the reduction of nausea, retching and vomiting was compared with placebo during and after stapedo- and tympanoplasty under local anaesthesia in a double-blind, prospective and randomized study. In the placebo group ($n = 29$), 69% of the patients were free from emetic symptoms during and 41% after the operation. The corresponding figures were 93% ($P < 0.05$) and 74% ($P < 0.05$) in the hyoscine group ($n = 27$). The patients in the placebo group needed more droperidol during and after operation ($P < 0.05$). The frequency of side effects was similar in both groups. In posturography the patients with emetic sequelae in the placebo group had a markedly deteriorated upkeep of posture ($P < 0.05$) measured as body sway velocities. A strong correlation was found between motion sickness and emetic sequelae after surgery, and patients with a history of motion sickness benefited most from hyoscine. (*Br. J. Anaesth.* 1996; **76**: 49–53).

Vomiting, nausea. Vomiting, antiemetics. Surgery, otolaryngological. Premedication, hyoscine. Drug delivery, transdermal.

Introduction

Hyoscine was found to reduce postoperative nausea and vomiting (PONV) in two recent studies after middle ear surgery under general anaesthesia [1, 2]. The percentages of patients suffering from PONV in the placebo groups were 80% and 62%. Although vertigo and dizziness are well known complications after stapedoplasty [3] no study has been published on emetic symptoms and middle surgery under local anaesthesia.

Assessment of earlier studies performed in our clinic indicated that stapedoplasty caused considerable PONV while tympanoplasty produced a little less. Transdermal hyoscine has been shown to be antiemetic both in motion sickness [4] and postoperatively after different types of surgery [1, 2, 5–9]. One of the many causes of PONV [10] may be increased stimulation of the vestibular apparatus by surgery, and this could be enhanced further by increased vestibular sensitivity caused by opioids [11, 12]. Any possible vestibular component to PONV and its modification by transdermal hyoscine might be revealed by computerized posturography [13, 14].

Thus, the present work was designed to study the occurrence of PONV and need for rescue antiemetics during and after stapedo- and tympanoplasties performed under local anaesthesia and the effect of transdermal hyoscine.

Patients and methods

Informed consent was obtained from 56 ASA class I–II patients, aged 21–55 yr, scheduled for stapedo- or tympanoplasty under local anaesthesia. Exclusion criteria included: regular or temporary use of antiemetic drugs, and vomiting or retching within 24 h before the operation. The Ethics Committee of the Otolaryngological Hospital approved the study.

Patients were allocated randomly to a placebo ($n = 29$) or a hyoscine ($n = 27$) group in a double-blind study. On the afternoon of the day before surgery, a history of motion sickness and PONV and the menstrual data [10, 15] were noted. Thereafter, on the basis of the randomization, either an inactive patch or an identical hyoscine patch (Scopoderm 0.5 mg 72 h^{-1}) was applied to the skin of the postauricular area opposite the operative side after cleansing the skin with diethyl ether. In order to secure the patch, it was covered by an adhesive tape.

Evaluation of postural stability by computerized posturography [16] was performed as follows: (1) before applying the test patch during the afternoon before operation, (2) before premedication on the morning of the operation, (3) 24 h after surgery and (4) 1 week after the operation. In posturography, the patient stands on a force platform connected to a computer. The system records the movement of the centre-point of forces (the sway path). The calculated length of the sway path during analysis gives the mean sway velocity [17]. The posturographies were made under a 3-min sequence, during which the recordings were made with both the eyes open and closed for 30 s after a period of initial stabilization for both eyes open and closed. Patients with uncompensated vestibular function before surgery (mean sway velocity over 3 cm s^{-1} during the control recording (1) with their eyes closed), were excluded from statistical processing of the results of posturography: two from the placebo group and four from the hyoscine group. The Romberg quotient is

a derived ratio between mean sway velocity values recorded in non-visual and visual conditions and it is used commonly to describe the effect of visual control on posture. The repeatability of the posturography as a test of postural stability has been shown to be good [18].

Before local anaesthesia the patients were questioned on the presence of sedation, dry mouth, anxiety, dizziness, blurred vision, urinary difficulties or other symptoms. Thereafter, the placebo group received glycopyrronium 0.2 mg i.v. and the hyoscine group received saline from identical syringes containing the same volume, each with its own code number in a double-blind manner.

Premedication comprised oxycodone 0.1 mg kg^{-1} i.m. 40–60 min before operation. Local anaesthesia was performed with lignocaine containing adrenaline. Fentanyl 1 µg kg^{-1} was given before local anaesthesia and thereafter during operation as 25-µg doses for analgesia. Diazepam in 2.5-mg doses was used for sedation, if needed. Monitoring before, during and after operation included arterial pressure with automatic oscillotonometer, electrocardiogram and haemoglobin oxygen saturation (Sp_{O_2}). During operation patients received oxygen 2–4 litre min^{-1} via nasal cannulae.

Postoperative pain was treated with diclofenac 1 mg kg^{-1} i.v. or with paracetamol 10 mg kg^{-1} suppositories in patients who could not tolerate diclofenac. In addition, oxycodone 0.05 mg kg^{-1} i.v. or 0.1 mg kg^{-1} i.m. was used if needed. (Note that diclofenac is registered in Finland for i.v. use, but this is not the case in all countries.)

A trained nurse, who was unaware of the nature of the study drug, enquired for vertigo and assessed the occurrence of nausea, retching and vomiting during operation and at the following times; 0–2, 2–6, 6–12, 12–18 and 18–24 h after the end of the surgery. If the patient experienced more than one symptom, for example both nausea and vomiting, she was listed as having vomited. During the first 0–2 h after surgery the patients were in the recovery room and thereafter in the ward. Droperidol 10 µg kg^{-1} i.v. or i.m. was given for vomiting, retching or prolonged nausea, at a minimum interval of 30 min. Vertigo was scored as follows: 0 = no vertigo, 1 = slight sensation of vertigo, 2 = strong sensation of vertigo, 3 = has to avoid head movement and 4 = has to keep eyes closed.

STATISTICS

ANOVA, followed by the Bonferroni/Dunn procedure, if appropriate, was used for parametric data, and the chi-square test with Yates' correction or Fisher's exact test for non-parametric data. Logistic regression analysis was used to find predictors for PONV. The Spearman rank correlation coefficient was applied to the posturography data. A P value less than 0.05 was regarded as significant.

Results

There were no significant differences in patient characteristics or details of the local anaesthesia between the groups (table 1). The number of female patients having normal menstrual cycles was 15 in the placebo group and 14 in the hyoscine group. The distribution of the patients between the different phases of the menstrual cycle was similar in both groups.

In logistic regression analysis the following variables were found to be predictors for PONV: sex ($P < 0.001$), vertigo score ($P < 0.001$), history of motion sickness ($P < 0.05$), treatment with hyoscine patch ($P < 0.05$) and the other variables studied were not predictors for PONV.

During operation 69 % of patients in the placebo group were devoid of nausea and vomiting and the corresponding value for the hyoscine group was 93 % ($P < 0.05$). No retching occurred during operation. Patients in the placebo group had more emetic episodes peroperatively than the patients in the hyoscine group ($P < 0.05$) (table 2).

During the first 24 h after surgery the number of patients having any emetic symptoms was less (7/27 *vs* 17/29, $P < 0.05$) in the hyoscine group than in the placebo group (table 2).

Both the number of patients needing and the number of doses needed of the rescue antiemetic (droperidol) was significantly higher in the placebo group during operation, in the ward (2–24 h) and for the whole study. There was no significant difference in the time from local anaesthesia to the need for droperidol (table 3).

Table 3 Need for rescue antiemetic (10 μg kg^{-1} droperidol) during and after operation of stapedo- and tympanoplasty under local anaesthesia (mean (SD)), * $P < 0.05$ between placebo and hyoscine groups. ** $P = 0.096$.

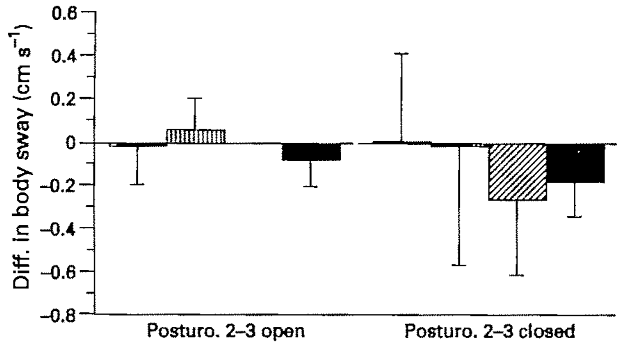

Figure 1 Differences in mean body sway in posturographies (Posturo.) 2 and 3 eyes open and closed, in the placebo and hyoscine groups when grouped in relation to retching and vomiting after surgery (mean, SD). □ = Placebo group with no retching and vomiting, ▥ = placebo group with retching and vomiting, ▨ = hyoscine group with no retching and vomiting, ■ = hyoscine group with retching and vomiting.

Posturographies 2 (in the morning before surgery) and 3 (24 h after surgery) revealed in the placebo group significantly more deterioration of postural stability in the patients suffering from retching and vomiting than in the patients without these symptoms. Both the differences in mean sway velocities ($P < 0.05$) and Romberg quotient ($P < 0.05$) had worsened, when rankings from differences in these recordings were assessed by Spearman rank correlation coefficient. In the hyoscine group there were no significant changes when postural stability was assessed in a similar fashion. There were no significant differences in the hyoscine group between the patients with or without emetic sequelae before and after administration of the hyoscine patch (posturographies 1 and 2). Figure 1 illustrates the mean differences in body sway velocities in different groups (posturographies 2 and 3), but it should be noted that statistically the *rankings* of the differences are assessed.

There were 12 patients in the placebo group and nine patients in the hyoscine group with a positive history of motion sickness and the respective values for negative history of PONV were 16 and 13. The cross-tabulated results of the correlations between treatment, history of motion sickness and history of PONV are shown in table 4. Hyoscine significantly increased the percentage of patients who were free of all emetic symptoms both during and after surgery ($P < 0.05$). The respective increase was also significant in relation to negative history of PONV and being symptom-free during surgery ($P < 0.05$). In the placebo group there was a positive correlation between a history of motion sickness and nausea and vomiting during ($P < 0.001$) and after surgery ($P < 0.005$). There was no significant effect of a history of motion sickness on nausea and vomiting in the hyoscine group, when assessed in a similar fashion. In all groups there was no correlation between positive histories of PONV and motion sickness.

Table 4 Percentage of patients free from all emetic symptoms in relation to histories of PONV (hPONV) and motion sickness (hMoSi), * $P < 0.05$ between placebo and hyoscine groups ** $P = 0.0524$.

	Placebo	Hyoscine
	During surgery free from all emetic symptoms (%)	
hMoSi negative	94	94
hMoSi positive	33	89*
hPONV negative	69	100*
hPONV positive	83	82
	After surgery free from all emetic symptoms (%)	
hMoSi negative	65	78
hMoSi positive	8	67*
hPONV negative	44	85**
hPONV positive	33	55

In the placebo group 14% of the patients reported sedation before local anaesthesia and the corresponding value was 4% in the hyoscine group. During the 24 h after surgery more patients in the placebo group reported vertigo (8/29) than in the hyoscine group (1/27, $P < 0.05$). There were no significant differences in side effects immediately before local anaesthesia between placebo and hyoscine groups and they varied between 0–11%.

Discussion

Transdermal hyoscine considerably increased the percentage of patients who were free from all emetic symptoms, and decreased the need for rescue antiemetic during and after stapedo- and tympanoplasties under local anaesthesia without increasing the frequency of side effects compared with the placebo group. The most clinically important finding was a reduced incidence of nausea and vomiting during operation, because emetic symptoms normally result in movement, which may lead to serious consequences during surgical manipulation in the middle ear.

The use of glycopyrronium in the placebo group, in order to diminish salivation and thus to reduce the possibility of head movements during ear microsurgery caused by swallowing, may raise doubts about the design of the study. However, glycopyrronium is unable to cross the blood-brain barrier [19] and those muscarinic receptor antagonists that are effective in reducing nausea and vomiting act by blocking central muscarinic receptors in afferent pathways of the vomiting reflex [20]. Glycopyrronium has been shown not to affect gastric emptying and intestinal transit times [21]. The overall percentage of placebo-treated patients reporting emetic symptoms in this study was also the same as that in two recently published studies on PONV after middle ear surgery under general anaesthesia [1, 2]. Drugs effective in motion sickness include centrally acting muscarinic receptor antagonists [22] and there are no data suggesting that glycopyrronium affects the vestibular system [23]. Furthermore, it was given approximately 4 min before local anaesthesia with lignocaine containing adrenaline and the increase in pulse rate was masked by the tachycardia caused by the local anaesthesia.

The results of this study are in agreement with earlier studies showing that transdermal hyoscine is an effective prophylactic against PONV [1, 2, 5–9]. In the present study, the patients in the placebo group with a history of motion sickness had a higher frequency of nausea and vomiting than the patients without motion sickness and this finding has also been reported elsewhere [1, 24, 25]. The reduction in nausea and vomiting in the hyoscine group, in relation to motion sickness may result from specific inhibition of the post-synaptic potential in the neurones of the vestibular nuclei [14]. This assumption is supported by the fact that in the placebo group there was a significant correlation between motion sickness and nausea and vomiting during and after surgery but this was not the case in the hyoscine group.

Posturography revealed that the patients in the placebo group not suffering from retching and vomiting, had better vestibulo-spinal function after surgery than those suffering from these symptoms. In the hyoscine group there was no difference in deterioration in postural stability between those without emetic and those with emetic sequelae (retching and vomiting), which also supports a direct action of hyoscine on the vestibular system [14].

In a recently published study on the effect of transdermal hyoscine on PONV after outpatient ear surgery there was, in common with this study, both more PONV and vertigo in the placebo group [2]. In a recently published study on postoperative nystagmus and nausea [26] there was a marked correlation between PONV and nystagmus, which is also caused by vestibular dysfunction. The recordings were made earlier than in our study: the first after the patient was oriented to time and space in the recovery room and the second soon after arrival in the short-procedure unit. As described earlier [1], because the frequency of PONV after ear surgery declines throughout the first 24 h after operation it is possible that posturography performed 24 h after surgery was too late to reveal the real magnitude of correlation between PONV and postural instability. Vestibular symptoms in the form of imbalance and occasional dizziness have been reported to last weeks after surgery [3].

Acknowledgement

I acknowledge the numerous discussions with the Professor in Otology, Ilmari Pyykkö, MD, during the preparation of the programme of posturography for this study, during assessment of the results of posturographies and during the revision of the manuscript.

Single dose i.v. tropisetron in the prevention of postoperative nausea and vomiting after gynaecological surgery

V. CAPOUET, C. DE PAUW, B. VERNET, D. IVENS, V. DERIJCKE, L. VERSICHELEN, H. VAN AKEN, B. ICKX, L. RITTER AND F. HULSTAERT

Summary

In a prospective, randomized, multicentre, double-blind, placebo-controlled study, we have compared the efficacy of a single i.v. dose of tropisetron 0.5 mg, 2 mg and 5 mg in the prevention of postoperative nausea and vomiting (PONV). We studied 385 ASA class I and II female patients undergoing abdominal or vaginal gynaecological surgery, including laparoscopy. Tropisetron or placebo were administered before a standardized general anaesthetic. The frequency of vomiting in the 24-h period after entry into the recovery room was reduced from 44% after placebo to 31%, 26% and 30% after tropisetron 0.5 mg, 2 mg and 5 mg, respectively ($P = 0.06$, $P = 0.009$ and $P = 0.043$; unadjusted). Compared with placebo, nausea was reduced from 55% to 46%, 34% and 46% ($P = 0.25$, $P = 0.003$, $P = 0.22$), and need for rescue treatment from 39% to 29%, 23% and 35% ($P = 0.13$, $P = 0.017$ and $P = 0.59$) for the same groups. Tropisetron 2 mg appeared to be the optimal dose for prophylaxis against PONV with a side-effect profile similar to that of placebo. (*Br. J. Anaesth.* 1996; **76**: 54–60)

Key words

Vomiting, nausea. Vomiting, antiemetics. Serotonin antagonist, tropisetron.

Postoperative nausea and vomiting (PONV) remain among the most common of anaesthesia-related adverse effects [1]. The aetiology of PONV is multifactorial and includes factors related to the characteristics of the patient, the type of surgery, type of anaesthetic and postoperative factors [2–5]. Antiemetic prophylaxis may be justified in patients who are at greater risk of developing postoperative nausea and/or vomiting [2]; these include patients with a history of previous postoperative emesis and women undergoing gynaecological procedures, e.g. laparoscopy.

Antiemetics with an antidopaminergic action such as metoclopramide and droperidol are often used in the control of PONV but their use is limited by side-effects including sedation, hypotension, extrapyramidal symptoms and dysphoria [6].

Tropisetron (Navoban, ICS 205-930, Sandoz Pharma Ltd, Switzerland) is a selective competitive 5-HT_3 receptor antagonist, which has low affinity for 5-HT_4 receptors [7] and little or no activity at the non-5-HT_3 receptors, such as α_1, α_2 and β_1 adrenoceptors, muscarinic and nicotinic cholinergic receptors, histamine H_1 and H_2 receptors and dopamine D_2 receptors [8]. At a dose of 5 mg once daily, tropisetron has been shown to be an effective and well tolerated agent for the prevention of chemotherapy-induced emesis [9]. The metabolism of tropisetron in humans is linked to the polymorphically expressed cytochrome *P-450* IID6 enzyme system. The elimination half-life of tropisetron is 8 h in fast metabolisers and even longer in slow metabolisers [10], which could make this agent suited to prevention of PONV using a single dose. A single i.v. dose of tropisetron 5 mg has been shown to reduce significantly the incidence of PONV after gynaecological surgery under general anaesthesia [11]. The aim of the present study was to determine if smaller doses of tropisetron would be effective compared with placebo in the prevention of PONV.

Patients and methods

This randomized, multicentre, placebo-controlled, double-blind study was carried out in eight hospitals in Belgium and was conducted with the approval of the local Ethics Committees. The study was explained to each patient and written or oral witnessed informed consent was obtained. We studied ASA grade I and II women, between 18 and 75 yr, undergoing abdominal or vaginal gynaecological surgery, including laparoscopy, under general anaesthesia. Patients were expected to remain in hospital for at least 6 h after surgery. Patients were excluded if they had vomited during the 24 h before surgery or if they had received antiemetics during

the same period. Patients were also excluded if they were expected to have a nasogastric tube after surgery, if they had a history of alcohol or drug abuse, if they were known to have hypersensitivity reactions, or if they were pregnant or lactating with the exception of those undergoing termination of early pregnancy combined with laparoscopic tubal ligation. Baseline information included height, weight, age, ethnic origin and days since start of last menstrual cycle. The current and past medical history of the patient was also recorded with special attention paid to motion sickness or PONV after general anaesthesia.

Patients were allocated randomly to one of the four treatment groups using a block size of 12 per centre. The study medication consisted of 5 ml ampoules containing 5 mg of tropisetron or perfectly matching placebo ampoules and was supplied to the centres in a sealed box containing a leaflet with instructions for preparation. The randomization number was printed on the box. A 5-ml syringe was prepared by the local pharmacist (in four centres) or a physician or nurse not participating in the study in any other way. In accordance with the instructions on the leaflet in the medication box 0.5 ml, 2 ml or 5 ml were obtained from the study ampoule and diluted with normal saline to a total volume of 5 ml. The double-blind character of the study was further assured by also having the three possible procedures performed for placebo.

The contents of the 5-ml syringe were then administered i.v. over 1 min before the start of induction of anaesthesia. Vital signs (systolic and diastolic arterial pressure and heart rate) were recorded immediately before, and 1 min after injection of the drug and 1 min after the start of induction.

Premedication was standardized at each centre and consisted of diazepam, alprazolam, lormetazepam or no premedication. All patients underwent tracheal intubation and received general anaesthesia including an induction agent (thiopentone), an opioid (fentanyl or sufentanil), and nitrous oxide supplemented with isoflurane. Neuromuscular block was facilitated with atracurium or vecuronium and reversed as appropriate with an anticholinesterase (neostigmine) with glycopyrrolium as the recommended anticholinergic agent. The choice of the opioid and the neuromuscular blocker was also standardized at each centre. The use of a nasogastric tube during surgery was allowed if removed by the end of the operation.

The duration of anaesthesia and the awakening time, i.e. the time between the end of administration of anaesthesia and the time of eye opening on request, were recorded with the level of consciousness after 30 min in the recovery room. The occurrence of emetic episodes in the operating room was also recorded. Postoperative analgesia was standardized. Patients could receive propacetamol, paracetamol or piritramide, an opioid analgesic. If the patient experienced PONV, the choice of the rescue treatment was at the discretion of the investigator. The first routine measurement of heart rate and systolic and diastolic arterial pressure after arrival in the ward was also recorded. In a single centre, electrocardiographic (ECG) recordings were obtained before surgery (baseline ECG), and 2 h (2-h ECG), 4 h (4-h ECG) and 24-h (24 h ECG) after administration of the study drug. Patients at that centre stayed in the recovery room for the 2-h and 4-h ECG.

In agreement with a study using a similar design [12] the main 24-h evaluation period for nausea and emesis began after the patient entered the recovery room and was capable of responding to a verbal command. This 24-h period was divided further into three assessment periods. The first period corresponded to the stay in the recovery room. The second period started when the patient left the recovery room and ended when 6 h of the 24-h period had passed. The third period covered the next 18 h. For the purpose of data collection no distinction was made between vomiting and retching. An emetic episode was defined as a single vomit or retch, or multiple vomits or retches separated in time by less than 1 min. Presence or absence of nausea was also recorded together with rescue treatment, if given. The patients were given diary cards on which to record the occurrence of emetic episodes, nausea and administration of antiemetic drugs. For the assessment of safety and efficacy the investigator used the patient's diary card and the observations of the nursing staff and questioned the patient directly. Day-case surgery patients remained in hospital during the first two assessment periods and were questioned by phone at the end of the 24-h observation period. In addition, a diary card completed by the patient was sent by mail to the study centre. Day-case surgery patients could be enrolled only in those centres where follow-up for the 6–24-h period could be guaranteed by the investigator.

ENDPOINTS AND STATISTICAL ANALYSIS

The primary efficacy variable of the study was the proportion of patients defined by the presence or absence of any emetic episodes over the 24-hour period regardless of rescue treatment given. A minimum sample size of 360 patients in four groups of 90 patients was selected to detect a 50 % reduction in the frequency of emetic episodes, from 40–50 % with placebo to 20–25 % with the optimal dose of tropisetron at the 5 % significance level with 80 % power. No interim analyses were planned or conducted.

For the primary efficacy variable the differences in proportions between treatment groups were tested by means of chi-square tests without continuity correction. A global test of all treatment groups against placebo was followed by pairwise tests comparing placebo with each dose of tropisetron. A closed-test procedure was used in order to ensure that the nominal level of significance was kept at 0.05 [13]. All tests were two-sided. Statistical analyses were performed using SAS version 6.08 under licence from SAS Institute (Cary, NC, USA).

Both the adjusted P values obtained using this closed test procedure and the unadjusted P values are reported. Secondary efficacy variables were the occurrence of nausea over the 24-h postoperative period, the administration of rescue treatment over the same period and the occurrence of emetic episodes over the 24-h period including events in the operating room. P values of the comparisons based on these secondary efficacy variables are reported with the caveat that their significance level must be adjusted to account for multiple testing.

Further exploratory analyses of possible prognostic factors were performed using logistic regression models. The following factors were considered: treatment group, centre, age, weight, history of PONV, motion sickness, days since last menses (< 8, 8–40, $\geqslant 40$ days), use of a benzodiazepine as premedication, type of surgery (laparoscopy, laparotomy), duration of anaesthesia, use of an anticholinergic before or during anaesthesia, use of postoperative opioids, and use of rescue treatment for nausea. Each factor was considered alone in the model, and then the final model was built by taking the most significantly related factor and adding the remaining factors not yet in the model until all significantly related factors had been included. The odds ratio and 95 % confidence intervals (CI) were calculated for the variables in the final model, both unadjusted, and adjusted for the other factors.

Results

CHARACTERISTICS OF THE PATIENTS AND THE ANAESTHESIA

Informed consent was obtained and study medication was prepared for a total of 391 sequential patients. The number of patients enrolled per centre varied between 33 and 70. Three patients withdrew their consent before administration of the study drug. Three ineligible patients were withdrawn from the study before administration of study medication because of a history of angioneurotic oedema, an ovarian carcinoma with metastases and a positive pregnancy test. The study medication was administered to a total of 385 patients in the 1-h period before the start of induction. In a single patient, induction followed 125 min after study drug administration because of unexpected delay in the surgery schedule. All 385 female patients were included in the analysis.

In this study 381 of 385 patients (99 %) were white. The groups were comparable in age, weight, height, days since last menstrual cycle and proportion of patients with a history of general anaesthesia and PONV or motion sickness (table 1).

The mean time between administration of study drug and the start of induction was 9 min and this was similar for all groups. In all four groups laparoscopy was the most common type of surgery (in 56 % of the patients), followed by abdominal hysterectomy (table 2).

Benzodiazepine premedication was administered to 72 % of all patients with the majority of these (60 %) receiving diazepam. Other benzodiazepines given included alprazolam (21 %), lormetazepam (16 %), midazolam (2 %) and lorazepam (in one patient). The mean doses were similar for all groups (diazepam 8.5 mg, alprazolam 0.8 mg, lormetazepam 3.3 mg). Anticholinergic premedication was used in five (5 %), three (3 %), six (6 %) and six (6 %) patients in the placebo, tropisetron 0.5-mg, 2-mg and 5-mg groups, respectively, and consisted of glycopyrronium ($n = 15$, mean dose 0.2 mg) or atropine 0.3 mg ($n = 5$).

The duration of anaesthesia (overall mean 77 min), the use of anaesthetics and postoperative opioids are detailed in table 3. All patients had induction of anaesthesia with thiopentone and received nitrous oxide supplemented with isoflurane. Atracurium or vecuronium was used as neuromuscular blocking agent. One patient undergoing breast surgery did not receive a neuromuscular blocker. In 111 patients (29 %) the neuromuscular blocking agent was antagonized using neostigmine at a mean dose of 1.6 mg, in all but two patients associated with an anticholinergic agent consisting of glycopyrronium (*n* = 102, mean dose 0.4 mg) or atropine (*n* = 7, mean dose 0.3 mg). All patients received opioids during anaesthesia and these consisted of sufentanil (in 55 %) or fentanyl. One patient received both agents. Opioids were antagonized using naloxone (mean dose of 73 µg) in four (4 %), five (5 %), two (2 %) and five (5 %) patients in the placebo, tropisetron 0.5-mg, 2-mg, and 5-mg groups, respectively. Postoperatively, opioids were given to approximately 70 % of the patients in each of the groups and consisted primarily of piritramide. Pethidine was used for three patients. Other postoperative analgesics consisted of propacetamol or paracetamol. Intraoperative bradycardia was treated with atropine in eight patients (mean dose 0.4 mg) and with glycopyrronium in seven patients (mean dose 0.4 mg). Eleven patients (3 %) received a gastric tube during anaesthesia.

The patients stayed in the recovery room for a mean of 140 min. Patients having day-case surgery

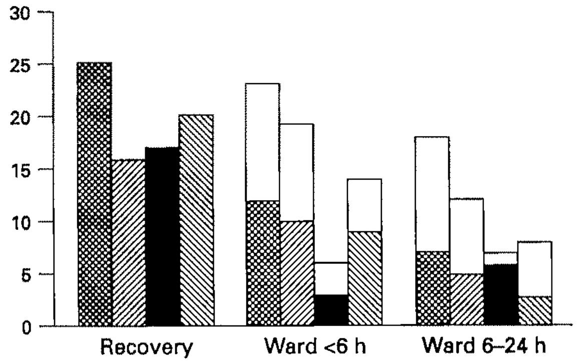

Figure 1 Percentage of patients with a first occurrence of emesis (first block) and percentage of patients with recurrence of emesis that started in a previous period (blank bars stacked on top) by assessment period in the placebo (▩) and tropisetron 0.5 mg (▨), 2 mg (■) and 5 mg (▧) groups.

represented 6 % of all patients (22 of 385) and were distributed evenly over the four treatment groups. All other patients remained in hospital for the full 24-h observation period.

EFFICACY RESULTS

In one patient the efficacy could not be assessed because of postoperative intragastric suction following intraoperative perforation of the intestinal wall by a laparoscope. The results for the primary endpoint and the secondary endpoints are listed in table 4. Both tropisetron 2 mg and 5 mg resulted in significant reduction in the incidence of vomiting compared with placebo. Vomiting or retching when the patient was still in the operating room after surgery occurred in three (3 %), three (3 %), three (3 %) and seven patients (7 %) in the placebo, tropisetron 0.5-mg, 2-mg and 5-mg groups respectively. When this incidence of vomiting is included in the 24-h period results, a significant decrease compared with placebo occurred only for the 2-mg dose. Compared with placebo the reduction in incidence of nausea and the use of rescue treatment were also significant for the 2-mg dose but not for the other doses of tropisetron tested.

Rescue treatment was administered to 19 % of all patients in the recovery room and to 18 % of all patients on the ward and consisted most frequently of alizapride (50 mg to 250 mg i.v.), followed by metoclopramide (10 mg to 40 mg i.v.). Six patients received droperidol 1.25 mg i.v. The mean doses of these agents given in the recovery room and on the ward were similar for all groups.

The frequency of first emetic episodes per assessment period are presented in figure 1, together with the frequency of recurrences of emesis that had started in a previous period. Fewer recurrences were seen in the second and third period for both the tropisetron 2-mg and 5-mg groups whereas the effect on first occurrence of vomiting in the first, second and third observation period was most pronounced for the tropisetron 0.5-mg, 2-mg and 5-mg doses, respectively.

The analysis of the subgroup of patients with a positive history of PONV revealed a frequency of vomiting in the placebo treatment group of 71 % (15 of 21 patients), which was reduced to 44 % (7 of 16 patients), 36 % (8 of 22 patients) and 41 % (9 of 22 patients) for the 0.5-mg, the 2-mg and the 5-mg doses, respectively. Furthermore, the subgroup analyses based on the use of a benzodiazepine as premedication, the duration of anaesthesia, the type of surgery, the presence or absence of motion sickness, the number of days since last menses, the use of an anticholinergic before or during anaesthesia and the use of postoperative opioids suggested that the efficacy of tropisetron was not restricted to a single subgroup.

The prognostic factors were included in a logistic model to find which ones were related most significantly to the primary outcome variable. The factors treatment, previous PONV and motion sickness were significant in the univariate models. The only factors which remained significant when considering combinations of factors were treatment, previous history of PONV and use of anticholinergics. There were no significant interactions. The adjusted odds ratio (95 % CI) of treatment compared with placebo were 0.53 (0.29, 1.0), 0.40 (0.21, 0.76) and 0.51 (0.27, 0.95) for tropisetron 0.5 mg, 2 mg and 5 mg, respectively. The adjusted odds ratio (95 % CI) associated with previous PONV was 2.41 (1.43, 4.07) and with use of anticholinergics 0.53 (0.32, 0.87).

SAFETY RESULTS

The recovery from anaesthesia measured by the waking time and the level of consciousness assessed 30 min after arrival in the recovery room was very similar in all four groups (table 5). All adverse events

Eye irritation	0	0	1	0
All adverse events:				
Patients with adverse events	10 (10%)	11 (11%)	5 (5%)	12 (13%)

are listed in table 6. There were no allergic reactions or other adverse events in the period between study drug administration and start of induction of anaesthesia. Most adverse events occurred only once. With perhaps the exception of headache, there was no increased frequency of adverse events in patients who received a higher dose of tropisetron.

Intraoperative bradycardia, reported as adverse event or treated with an anticholinergic, did not occur more frequently in any of the tropisetron groups compared with placebo, nor did heart rate, systolic and diastolic arterial pressure show a differential pattern of response to the anaesthesia for the four study groups. There were five cases of intraoperative hypertension documented as adverse event, distributed over all treatment groups, and one case of postoperative hypotension, which occurred 12 h after administration of tropisetron 5 mg in a patient suffering from severe nausea.

Four ECG recordings per patient were obtained in a single centre for 47 patients. There were no ECG abnormalities other than a single case of a transient first degree AV block and a transient QTc prolongation in another patient, both observed in the immediate postoperative period. The patient showing a transient first degree AV block already had a PQ/PR interval at baseline of 0.18 s after a history of complete thyroidectomy for Hashimoto thyroiditis with treatment-resistant hyperthyroidism. This patient had received tropisetron 2 mg. The patient with the transient prolongation of the QTc for the 2-h ECG and the 4-h ECG had received tropisetron 0.5 mg and had a 'double hump' aspect of the T wave at baseline.

Discussion

In accordance with the recommendations published by Korttila [14] we conducted a double-blind, placebo-controlled, comparative study with a sample size large enough to detect small differences and permit an even distribution of confounding factors that affect emesis among the study groups.

Our data show that a single dose of tropisetron 2 mg was effective in the prophylaxis of PONV and that the results for the high-risk subgroup of patients with a positive history of PONV are consistent with the overall results. Both tropisetron 2 mg and 5 mg resulted in a significant reduction in vomiting compared with placebo for the main 24-h period. The differences between the results for the three doses of tropisetron were, however, not large. For practical reasons and given the wide therapeutic index of tropisetron, the traditional population-based approach to dose selection was used in this study. Larger differences between the doses of tropisetron tested would perhaps have indicated a clearer dose response relationship.

Although the numbers are small, the retching and vomiting associated with the removal of the tracheal tube in the operating room at the end of anaesthesia was clearly not suppressed by tropisetron. As more of these events occurred in the 5-mg dose group, the difference between placebo and the 5-mg dose was non-significant when these events were added to the main 24-h results (table 4). Figure 1 suggests that the efficacy of tropisetron was sustained beyond the first 6 h after surgery. This is in agreement with the relatively long half-life of tropisetron and supports the use of a single dose of tropisetron to cover the full 24-h period.

5-HT$_3$ receptor antagonists are not general antiemetics. Although 5-HT_3 receptor antagonists are beneficial in abdominal procedures, because these procedures may release 5-HT and activate visceral afferent pathways or the area postrema in a similar way to that proposed for anticancer therapies, it has been suggested that 5-HT_3 antagonists might be less effective in ear, nose and throat or ocular surgery [15]. Clinical trials with tropisetron are required to test this hypothesis.

As PONV is a multifactorial problem we have used logistic regression models to estimate factors predictive of response. Of interest was the composition of the final logistic regression model, in which use of an anticholinergic was retained as associated with a lower incidence of PONV, independent of the effect of tropisetron and thus suggesting that the combination of both type of drugs could be more effective in preventing PONV than each drug alone.

In this study we administered tropisetron before induction in the hope of blocking the effect of serotonin released during surgery. This is in contrast with a previous study [11] where tropisetron was administered shortly before wound closure, when most of the serotonin that activates the receptors, implicated in nausea and vomiting reflexes, may already have been liberated. In retrospect, and considering that the anaesthetic technique used was not identical in the two studies, the timing of administration of tropisetron did not seem to be a major determinant of efficacy.

Dose comparative studies in the prevention of PONV have been reported for ondansetron [12] and recently also for granisetron [16], two other 5-HT_3 antagonists. These studies were also conducted mainly in female patients undergoing abdominal gynaecological surgery. As was the case for tropisetron in this study, the minimum dose of ondansetron and granisetron found to be effective for prevention of PONV was lower than the dose used in the setting of cancer chemotherapy. Although the frequency of emesis in the placebo group was slightly lower in our study compared with a study with ondansetron [12], the extent of reduction of PONV by both agents seemed to be of the same order of magnitude. As was reported for ondansetron [12], our data also suggest that the effect of 5-HT_3 antagonists on vomiting might be more pronounced than the effect on nausea, which is not necessarily a low-level stimulation of the vomiting reflex. Nausea is also more difficult to assess than vomiting in the postoperative period. As PONV is a multifactorial problem, only correctly designed comparative studies allow for direct comparison of efficacy and safety of other 5-HT_3 antagonists with tropisetron.

In this study there are few adverse events. The cardiovascular events could be explained in the context of the anaesthesia and the surgery and did not indicate a dose-relationship or a cardiovascular effect different from placebo. The asymptomatic and transient ECG findings in the immediate postoperative period consisting of a single case of a first degree AV block and a prolonged QT interval in another patient may be explained by the patient condition and the anaesthesia [17, 18].

Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section

D. G. THOMAS, S. C. ROBSON, N. REDFERN, D. HUGHES AND R. J. BOYS

Summary

Thirty-eight healthy women undergoing elective Caesarean section under spinal anaesthesia at term were allocated randomly to receive boluses of either phenylephrine 100 μg or ephedrine 5 mg for maintenance of maternal arterial pressure. The indication for administration of vasopressor was a reduction in systolic pressure to ⩽ 90% of baseline values. Maternal arterial pressure (BP) and heart rate (HR) were measured every minute by automated oscillometry. Cardiac output (CO) was measured by cross-sectional and Doppler echocardiography before and after preloading with 1500 ml Ringer lactate solution and then every 2 min after administration of bupivacaine. Umbilical artery pulsatility index (PI) was measured using Doppler before and after spinal anaesthesia. The median (range) number of boluses of phenylephrine and ephedrine was similar; 6 (1–10) *vs* 4 (1–8) respectively. Maternal systolic BP and CO changes were similar in both groups, but the mean [95% CI] maximum percentage change in maternal HR was larger in the phenylephrine group (−28.5 [−24.2, −32.9]%) than in the ephedrine group (−14.4 [−10.6, −18.2]%). As a consequence atropine was required in 11/19 women in the phenylephrine group compared with 2/19 in the ephedrine group ($P < 0.01$). Mean umbilical artery pH [95% CI] was higher in the phenylephrine group (7.29 [7.28–7.30]) than in the ephedrine group (7.27 [7.25–7.28]). The results of the present study support the use of phenylephrine for maintenance of maternal arterial pressure during spinal anaesthesia for elective Caesarean section. (*Br. J. Anaesth.* 1996; **76**: 61–65)

Hypotension can occur during spinal anaesthesia for Caesarean section despite fluid loading and adoption of the tilted supine position, with consequent risk of fetal acidaemia [1]. Ephedrine is considered the vasopressor of choice for treatment of hypotension although even prophylactic infusion of ephedrine does not reliably prevent maternal hypotension and fetal acidaemia [2].

Alpha-adrenergic agonists are an effective treatment of post-spinal hypotension but their use during pregnancy has been limited by concerns about uteroplacental blood flow (UPBF) [3, 4]. Two previous randomized studies have compared infusion of phenylephrine and ephedrine for prevention of post-spinal hypotension [5, 6]; no difference was found in umbilical artery pH between the groups, although Hall and colleagues [6] found that phenylephrine was less effective in maintaining systolic arterial pressure. Only one previous study has compared boluses of ephedrine or phenylephrine for treatment of post-spinal hypotension [7]. Phenylephrine was found to be equally effective as a vasopressor and its use was not associated with an increase in fetal acidaemia. However, maternal haemodynamic assessment was confined to measurement of arterial pressure.

Combined cross-sectional and Doppler echocardiography provides an accurate non-invasive method of measuring cardiac output (CO) in pregnancy [8, 9]. Doppler ultrasound can also be used to assess the fetal umbilical circulation and umbilical artery flow velocity waveform indices have been shown to be superior to cardiotocography in predicting fetal compromise [10]. It has been shown previously that changes in both of these variables, unlike changes in arterial pressure, correlate with umbilical artery pH at delivery [11].

The purpose of this study was to compare maternal and fetal haemodynamic changes, and umbilical artery pH, in subjects allocated randomly to receive phenylephrine or ephedrine for treatment of hypotension during spinal anaesthesia for elective Caesarean section.

Patients and methods

The study was approved by the Newcastle Health Authority and University of Newcastle-upon-Tyne Joint Ethics Committee. All subjects gave informed

written consent. We studied 40 healthy women with an uncomplicated singleton pregnancy undergoing elective Caesarean section at term. The number of subjects was calculated to detect a difference in umbilical artery pH of 0.05 units as being significant at the 5 % level with 80 % power [12]. For the power calculation, we assumed a standard deviation of 0.05 pH units [13]. Randomization using opaque envelopes was performed by the pharmacy department which then issued coded 10-ml syringes containing either ephedrine 5 mg ml^{-1} or phenylephrine 100 µg ml^{-1}. Two subjects were excluded after randomization because of failure to obtain satisfactory Doppler waveforms. Characteristics of the 38 subjects studied are shown in table 1.

Each subject received oral ranitidine 150 mg on the evening before and on the morning of surgery. A volume of 30 ml sodium citrate 0.3 mol $litre^{-1}$ was given before induction of spinal anaesthesia. Ringer lactate solution 1500 ml was infused rapidly through a 14-gauge i.v. cannula and continued thereafter at a rate of approximately 10–15 ml min^{-1}. With patients in the sitting position 2.5 ml of bupivacaine 0.5 % with 8.0 % dextrose was given via a 24-gauge Sprotte needle at either L2-3 or L3-4. Immediately after administration of local anaesthetic solution the patient was placed in a full right lateral position for 2 min. The subject was then rolled transiently into full left lateral position before being placed in the left modified supine position until delivery. Dermatomal level of anaesthesia was assessed by thermal discrimination 15 min after induction of anaesthesia. Inspired air was supplemented with oxygen at 5 litre min^{-1} from induction of anaesthesia until clamping of the umbilical cord.

Arterial pressure was measured by an automated oscillometric technique (Accutor). Baseline systolic arterial pressure (SAP) was taken as the lowest of six readings during rest before induction of anaesthesia. After injection of local anaesthetic arterial pressure was measured at 1-min intervals. Whenever SAP decreased to less than 90 % of the baseline 1 ml of vasopressor was administered. Maternal heart rate was monitored using finger pulse oximetry. On each occasion that maternal heart rate decreased to below 60 min^{-1} atropine 0.3 mg i.v. was administered.

Maternal ascending aortic flow velocities were recorded in the left modified supine position using a 2 MHz continuous wave Doppler transducer (Doptek) placed in the suprasternal notch [8]. Recordings were made before and after fluid preloading, and then at 3, 5, 7, 9, 11, 13 and 15 min after administration of intrathecal bupivacaine. A spectral analyser performed fast Fourier transform analysis of the Doppler signal and the output was converted to velocity according to the Doppler equation. The angulation of the ultrasound beam was adjusted until the highest velocities with the least spectral dispersion were obtained; these were then stored in the computer memory and it was assumed that the recorded velocities were those at the aortic orifice and that the beam was parallel with flow. Heart rate (HR) and systolic velocity integral (area under the velocity curve) were calculated automatically by the computer. For the systolic velocity integral (SVI) calculations were made using 15/16 of the maximum frequency in order to exclude high-frequency artefacts. Minute distance (the product of HR and SVI) was averaged over 4–6 consecutive cardiac cycles. Systolic aortic annulus diameter was measured in the parasternal long axis plane using a 5-MHz cross-sectional transducer (Hewlett-Packard). Diameters were measured from the leading edge of the anterior wall to the leading edge of the posterior wall [8]. The average of three measurements before anaesthesia was used to calculate aortic cross-sectional area and this value was used for all calculations of cardiac output. Cardiac output was calculated as the product of minute distance and aortic cross-sectional area.

Umbilical artery flow velocity waveforms were measured using a 4-MHz continuous wave Doppler transducer [14]. Fast Fourier transform analysis of the Doppler signal was performed by a separate spectral analyser (Doptek). Fetal heart rate (FHR) and pulsatility index (PI), the difference between peak systolic and end diastolic velocities divided by the average velocity [15] were calculated automatically with the computer. The average of 4–6 consecutive cycles was used for each determination. Umbilical artery PI was measured before and then 15 min after spinal anaesthesia.

At delivery the umbilical cord was double-clamped and 1-ml samples of umbilical vein and artery blood obtained. Each sample was heparinized with 0.1 ml of heparin (1000 iu ml^{-1}) and acid/base analysis performed within 5 min of cord clamping (Radiometer ABL-30). Apgar scores at 1 and 5 min after delivery were recorded by the attending paediatrician, who was unaware of the vasopressor used.

STATISTICAL ANALYSIS

Differences between groups were compared using Student's *t*-test for normally distributed data, and the Mann-Whitney test for non-parametric data.

Table 1 Patient characteristics. Figures are means (95 % confidence intervals)

	Ephedrine	Phenylephrine
Maternal age (yr)	27.4 (25.3, 29.5)	30.0 (27.9, 32.1)
Maternal height (m)	1.61 (1.57, 1.65)	1.57 (1.54, 1.60)
Maternal weight (kg)	71.8 (67.3, 76.4)	71.0 (66.8, 75.2)
Gestational age (weeks)	38.7 (38.4, 39.0)	38.7 (38.3, 39.0)
Birth weight (kg)	3.27 (3.09, 3.45)	3.27 (3.07, 3.48)
Indication for Caesarean section:		
Breech presentation	4	2
Previous Caesarean section	15	17

Table 2 Maternal haemodynamic data. Figures are mean (95 % confidence intervals) or median (range)*. SAP = systolic arterial pressure)

	Ephedrine	Phenylephrine
Baseline SAP (mm Hg)	120 (114, 126)	126 (121, 131)
Maximum change in SAP (%)	−22.2 (−26.0, −18.4)	−23.1 (−27.3, −18.4)
Number of occasions on which SAP fell by > 20 %*	0 (0, 4)	0 (0, 6)
Number of boluses of vasopressor used*	4 (1, 8)	6 (1, 10)
Baseline cardiac output (litre min^{-1})	6.68 (6.21, 7.16)	6.34 (5.72, 6.97)
Cardiac output after preload (litre min^{-1})	7.95 (7.27, 8.64)	7.87 (7.08, 8.65)
Maximum change in cardiac output (%)	−5.6 (−10.2, −0.9)	−8.9 (−14.6, −3.1)
Baseline maternal heart rate (beat min^{-1})	87 (83, 91)	89 (83, 95)
Maximum change in maternal heart rate (%)	−14.4 (−18.2, −10.6)	−28.5 (−32.9, −24.2)
Subjects requiring atropine (HR < 60)	2	11

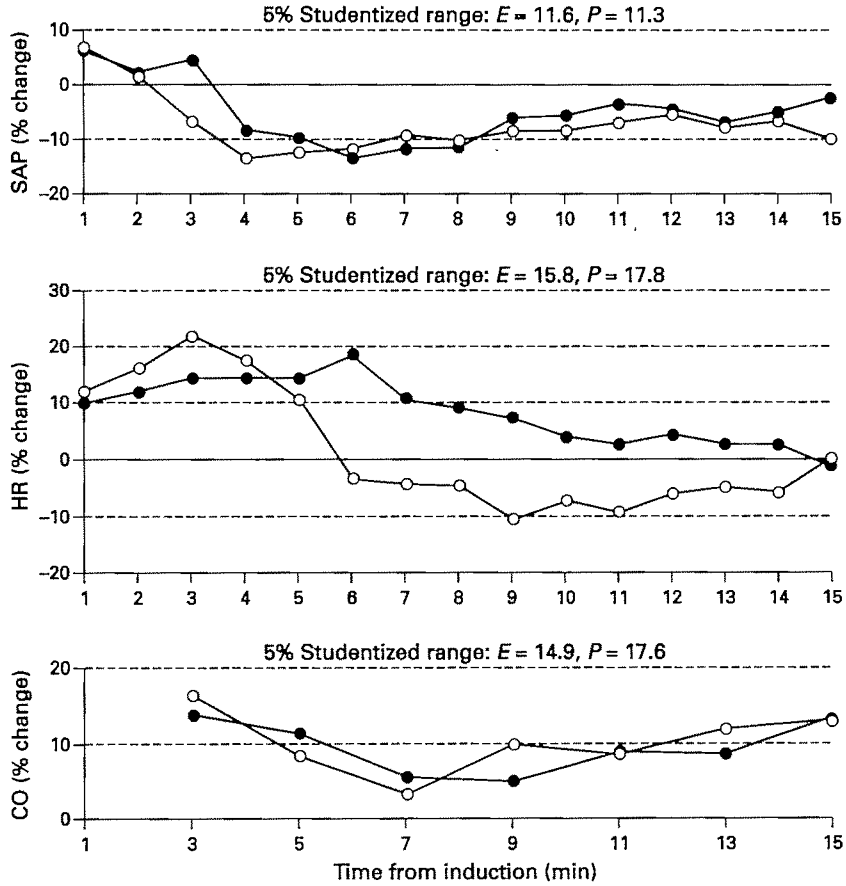

Figure 1 Mean percentage changes in systolic arterial pressure (SAP), heart rate (HR) and cardiac output (CO) from baseline values after induction of spinal anaesthesia in the ephedrine (●) and phenylephrine (○) groups, together with the respective Studentized ranges.

Comparison of proportions was performed using Fisher's exact test. Repeated measures analysis of variance was performed for each haemodynamic variable. To overcome the problem of multiple significance testing the differences between time points within the two groups were compared using the Studentized range at the 5 % level:

$$\text{Range} = q_{(v)} \times (s^2/\sqrt{n})$$

where $q_{(v)}$ = critical value for comparing two time points; s^2 = residual mean square with v degrees of freedom, n = number of subjects. The association between the number of doses of vasopressor and umbilical artery pH was assessed by Pearson's correlation coefficient. Results are presented as mean (95 % confidence interval), except where stated.

Results

Sensory block to T2–T4 was produced in all subjects by 20 min after injection of bupivacaine. There was no significant difference in the mean uterine incision to delivery (UD) interval in the two groups (ephedrine: median 72 [range 30–236] s, phenylephrine: median 57 [range 20–161] s). One subject in the ephedrine group had a UD interval of > 180 s, although the umbilical artery pH was normal (7.26).

Baseline haemodynamic measurements were similar in both groups (table 2). Cardiac output increased after fluid pre-loading in both groups. The maximum decrease in haemodynamic measurements, expressed as a percentage of the baseline value, is shown in table 2. Although there were no significant dif-

Table 3 Fetal data. Figures are mean (95% confidence interval)

Apgar < 7 at 1 or 5 min	0	0

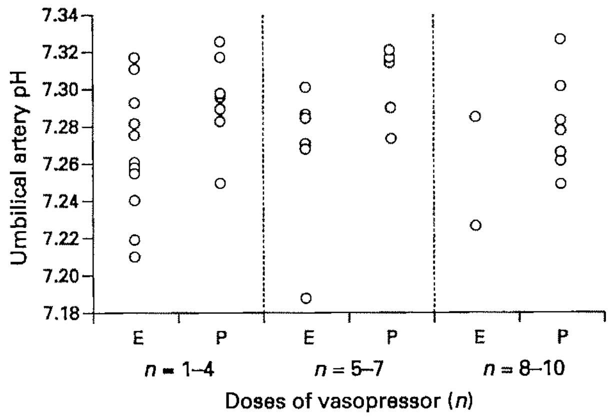

Figure 2 Effect of vasopressor use (number of doses of vasopressor given) on umbilical artery pH in the ephedrine (E) and phenylephrine (P) groups.

ferences in systolic pressure and CO, the maximum reduction in HR was greater in the phenylephrine group. As a result, more women required atropine (11/19, $P = 0.005$). The frequency of hypotension (SAP < 80% of baseline) and the requirement for vasopressor treatment was similar in the two groups (table 2).

The mean percentage changes in SAP, HR and CO after induction of spinal anaesthesia in the two groups, together with the respective Studentized ranges, are shown in figure 1. Systolic arterial pressure was reduced at 6–7 min in the ephedrine group, and at 4–6 min in the phenylephrine group. After an initial increase heart rate decreased in both groups. There was no significant change in cardiac output in either group.

Fetal data are presented in table 3. Umbilical artery pH was significantly higher in the phenylephrine group. Only one infant (in the ephedrine group) had an umbilical artery pH below 7.20. No apparent relationship was observed between umbilical artery pH and maximum percentage change in SAP (ephedrine $r = 0.08$, phenylephrine $r = 0.38$) or maximum percentage change in CO (ephedrine $r = 0.42$, phenylephrine $r = 0.15$). Baseline umbilical artery PI and fetal heart rate were comparable in the two groups. There was a small but statistically significant reduction in fetal heart rate in the phenylephrine group. No infants had Apgar scores of less than 7 at each time point.

The relationship between the number of doses of vasopressor required and umbilical artery pH is shown in figure 2. There was no significant correlation between the number of doses of either vasopressor and umbilical artery pH (ephedrine $r = -0.11$, phenylephrine $r = -0.22$).

Discussion

Hypotension is the most important complication of spinal anaesthesia and prompt effective treatment is considered essential to prevent fetal acidaemia. The results of the present study suggest that phenylephrine is as effective as ephedrine in restoring maternal arterial pressure during spinal anaesthesia and does not have detrimental effects on fetal haemodynamic state or umbilical artery pH. Although the incidence of maternal bradycardia was increased in women given phenylephrine there were no significant differences in maternal cardiac output between the two groups.

The present results confirm those reported in several previous studies [5–7] on the safety of phenylephrine in pregnancy. Alahuhta and colleagues [5] gave an initial bolus of ephedrine 5 mg or phenylephrine 100 μg when sensory analgesia had reached T5. This was followed by an infusion of 50 mg h^{-1} and 1000 μg h^{-1} respectively with further boluses if systolic arterial pressure decreased by 10 mm Hg from baseline. Although uteroplacental PI values increased following administration of phenylephrine (mean dose 488 (range 334–767) μg) there was no change in fetal heart rate or fetal Doppler indices. Umbilical artery pH was similar in both groups. Hall and colleagues [6] compared a prophylactic infusion of phenylephrine 10 μg min^{-1} with ephedrine 1 or 2 mg min^{-1} supplemented by 20-μg or 6-mg boluses respectively if systolic arterial pressure decreased by 20% from baseline. Although phenylephrine (mean dose 490 (range 300–680) μg) was less effective in maintaining systolic arterial pressure the umbilical artery pH was comparable in all three groups. Moran and colleagues [7] gave ephedrine 5–10 mg or phenylephrine 40–80 μg when systolic arterial pressure decreased by more than 5 mm Hg from baseline values. Boluses were repeated to maintain systolic arterial pressure above 100 mm Hg. Phenylephrine (total dose 335 (SD 31) μg) had similar vasopressor efficacy as that of ephedrine. The umbilical artery pH was significantly higher in the phenylephrine group.

At term the uterine vascular bed is maximally vasodilated and unable to autoregulate when perfusion pressure is reduced [16]. Consequently, a high adrenoceptor density renders uteroplacental blood flow (UPBF) potentially vulnerable to vasoconstriction induced by α-adrenergic agonists. Indeed, infusion of phenylephrine at 8 μg kg^{-1} min^{-1} has been reported to reduce ovine UPBF by 50 % [17]. However, the relationship between phenylephrine dose and uterine vascular resistance (UVR) is not linear and dramatic increases in UVR seem only to appear with doses greater than 100 μg min^{-1} [4]. Thus, the satisfactory fetal outcome in human studies may simply reflect the lower doses used, although it is worth noting that three women in the present study were given a total dose of 1000 μg phenylephrine. The umbilical artery pH values were 7.33, 7.30 and 7.25, the first being the highest in the whole study.

More than 50 % of women given phenylephrine in the current study developed significant bradycardia. A reduction in heart rate is a consistent effect in phenylephrine-treated women [5–7] although only Hall and colleagues [6] encountered bradycardia requiring treatment with atropine (heart rate < 40 min^{-1} in 2/10 subjects). Bradycardia could be caused by cardiac sympathetic denervation associated with high spinal block or a secondary baroreflex response to vasopressor-induced hypertension. In the current study there was no difference in extent of anaesthesia achieved. We were unable to find any relationship between either bradycardia or use of atropine and a hypertensive response to phenylephrine. This suggests that phenylephrine-associated bradycardia was caused by cardiac sympathetic denervation masked in the ephedrine group by the chronotropic effect of this β-adrenergic agonist.

Cardiac output was measured by combined Doppler and cross-sectional echocardiography. Values before and after fluid preloading are in close agreement with those published previously [11, 18]. In the present study initial aortic diameter measurements were used for all calculations of CO. We feel this is justified as aortic diameter is unlikely to change significantly during regional anaesthesia for Caesarean section [11, 18]. Umbilical artery Doppler waveforms were used to assess fetal wellbeing. In contrast with a previous study [11], we found no change in UAPI during spinal anaesthesia. Changes in previously normal umbilical artery waveform indices are generally associated with reductions in UPBF sufficient to cause fetal acidosis [19]. Thus the difference in UAPI results may reflect the lower UA pH in our earlier study.

Acknowledgements

David Thomas was supported by a research grant from the Northern Regional Health Authority. Doppler equipment was kindly loaned by Dr S. Hunter, Freeman Hospital, Newcastle-upon-Tyne and Mr J. Spencer, University College Hospital, London. Randomization and coding were performed by Mrs P. Sharma in the pharmacy department. This project could not have been completed without the help of our anaesthetic sister, Mrs M. Myles.

A double-blind comparison of 0.25% ropivacaine and 0.25% bupivacaine for extradural analgesia in labour

J. M. EDDLESTON, J. J. HOLLAND, R. P. GRIFFIN, A. CORBETT, E. L. HORSMAN AND F. REYNOLDS

Summary

Ropivacaine is a new aminoamide local anaesthetic. Compared with bupivacaine, ropivacaine possesses a higher threshold for systemic toxicity and a high selectivity for sensory fibres. We have compared prospectively these two agents in a concentration of 0.25% for extradural analgesia in labour. A total of 104 parturients requesting extradural analgesia were randomized to receive either ropivacaine or bupivacaine. The women in the bupivacaine group required more top-up doses to maintain analgesia (median 3.0 *vs* 2.0) ($P < 0.05$). The onset of sensory block, quality of analgesia, ultimate level of maximum sensory block and maternal satisfaction were similar in both groups. The incidence, intensity and duration of motor block were slightly but not significantly less in the ropivacaine group. The ropivacaine group had a higher incidence of spontaneous vaginal delivery (70.59% *vs* 52.00%). There was no significant difference in neonatal outcome as assessed by Apgar scores, umbilical acid–base status and neurological and adaptive capacity score at 2 and 24 h after delivery. We conclude that ropivacaine and bupivacaine in a concentration of 0.25% produced comparable analgesia for pain relief of labour with no detectable adverse effect on the neonate. (*Br. J. Anaesth.* 1996; **76**: 66–71)

Key words

Anaesthesia, obstetric. Anaesthetic techniques, extradural. Anaesthetics local, bupivacaine. Anaesthetics local, ropivacaine.

Extradural block is an effective means of providing analgesia in labour. However, all local anaesthetics used to date have significant disadvantages. For example, motor block results in decreased maternal mobility and satisfaction with the technique and may contribute to delay in the second stage of labour [1, 2] and postpartum backache [3]. Sympathetic block on the other hand may cause hypotension.

Serious maternal cardiotoxicity has been reported in the USA after inadvertent i.v. injection of bupivacaine [4]. Cardiac arrest, if it occurs, is resistant to treatment and has resulted in maternal deaths [5], although this has not been reported in the UK. In contrast, lignocaine is described as less cardiotoxic than bupivacaine [6]. Top-up doses are less likely to cause late decelerations in fetal heart rate [7] and its duration of action is shorter than that of bupivacaine. Repeated doses result in cumulative toxicity and tachyphylaxis. Scanlon and colleagues [8] suggested that lignocaine, administered extradurally, can result in the birth of "floppy but alert" babies (although his findings have been refuted by others) [7, 9, 10].

Recent attempts have been made to overcome these problems using either infusions of local anaesthetic rather than intermittent boluses [9, 11] or mixtures of dilute local anaesthetics with opioids [12–14]. There is no evidence of maternal benefit from using bupivacaine as the sole agent in extradural infusions and indeed extradural infusions of bupivacaine may result in more fetal heart rate decelerations than intermittent top-up doses [11].

Ropivacaine is a new aminoamide local anaesthetic with a structure closely related to bupivacaine and mepivacaine. Unlike bupivacaine (which is a racemic mixture), ropivacaine is a single enantiomer. It is the *S* isomer of *N*-propyl pipecholyl xylidine. Modern racemic local anaesthetics tend to be vasodilators at high and vasoconstrictors at lower concentrations. Ropivacaine is a vasoconstrictor over a wide range of concentrations [15].

In preclinical studies, ropivacaine was shown to have less central nervous and cardiovascular system toxicity than bupivacaine [16–18]. Ropivacaine is less lipid soluble than bupivacaine [19] but has similar protein binding. Its duration of action after extradural administration has been reported as being only slightly less than that of bupivacaine [20] but its shorter systemic half-life should make repeated doses potentially safer [21]. It has greater selectivity for sensory fibres compared with other local anaesthetics and consequently should be associated with less motor block [16, 22]. In addition, inadvertent i.v. injection is likely to produce less cardiac sequelae compared with bupivacaine, but the threshold for convulsions is similar [23].

All of these properties suggest that ropivacaine may be superior to bupivacaine in obstetric analgesia and we have examined this hypothesis in the present study.

Patients and methods

The study was conducted at two centres with similar procedures. Approval was obtained from the hospital Ethics Committees. Written informed consent was obtained from the patients before onset of painful labour. We studied 104 healthy women, aged 18 yr or more, requesting extradural analgesia.

All patients were in established labour and had a singleton healthy pregnancy (36–42 weeks' gestation) with a vertex presentation and a healthy fetal heart rate pattern on cardiotocography. Patients were excluded if the mother had been given more than a single dose of pethidine 125 mg, was greater than 110 kg in weight, less than 150 cm tall, expected fetal weight was < 2.5 kg or the fetus had a suspected abnormality.

Patients were allocated randomly to one of two groups. Group A received bolus doses of 0.25% ropivacaine and group B bolus doses of 0.25% bupivacaine. The drugs were in coded ampoules and the investigators were blinded to the contents. The randomization process was stratified to take into account parity of the patients. Nulliparous parturients received numbers starting from 1 and multiparous parturients from 80 downwards.

An i.v. infusion was established and at least 500 ml of Hartmann's solution was given before extradural block. With the mother in either the sitting or left lateral position, an extradural catheter was inserted in the lumbar region using the loss of resistance technique; 2–3 cm of catheter was left in the extradural space. A test dose of 5 ml of study drug was administered via the extradural catheter. Two minutes later another 5 ml was given. If analgesia was inadequate, the patient received an additional 5 ml of drug extradurally 10 min later.

Subsequently, top-up doses of 10 ml were administered as necessary by the midwife. The minimum time between top-ups was 15 min. The maximum amount of study drug a patient could receive was 95 ml, which corresponded to eight top-up doses. The maximum amount allowed in any 3-h period was 70 ml.

Hypotension was defined as systolic arterial pressure < 90 mm Hg or a reduction in arterial pressure > 30 mm Hg. A hypotensive episode was treated by increasing the rate of the i.v. infusion, positioning the patient on her left side and, if necessary, administering ephedrine. Uterine activity was monitored with an external abdominal transducer and fetal heart rate was recorded using either a scalp electrode or an external ultrasound detector. Oxytocin infusion and Entonox were given as appropriate during the study.

Onset of analgesia was assessed using a pain relief score with each contraction following the initial top-up (1 = no relief; 2 = little relief; 3 = a lot of relief; 4 = complete relief). A score of 3 or 4 was considered satisfactory. Assessment was discontinued when the patient decided analgesia was satisfactory. In addition, a visual analogue pain score (VAS) was recorded before extradural analgesia and then every 15 min until the infant was born.

Assessment of both sensory and motor block was made every 30 min using either ice or ethyl chloride and the Bromage score, respectively. Measurements were continued until return of normal sensation and motor function (Bromage motor score of 0).

The duration of the first and second stages of labour, mode of delivery and birth weight were recorded. In addition, Apgar scores were recorded at 1 and 5 min and umbilical arterial and venous blood samples were obtained at delivery from a clamped section of cord for assessment of $P\text{O}_2$ and pH.

Neurological and adaptive capacity (NAC) scores were recorded at 1.5–2.5 h and 22–26 h after birth. All of these observations were performed by the research fellow in each centre. The NAC score gives a numerical score with a maximum of 40, and an NAC score $\geqslant 35$ is considered to denote a vigorous baby [24].

Patients were withdrawn from the study if analgesia was not satisfactory, the maximum dose of local anaesthetic allowed by the study design was exceeded, the study lasted more than 24 h or delivery was by rotational forceps or Caesarean section.

The mothers and babies were visited daily during their hospital stay and any adverse events were recorded. A general assessment of overall satisfaction with the technique was also recorded. Further follow-up was made by letter or telephone 2–3 weeks after delivery.

STATISTICAL ANALYSIS

Two approaches to the statistical analysis were used: a "per design" analysis and an "all patients treated" analysis. The "per design" (PD) approach was used for analysis of efficacy and the "all patients treated" (APT) approach for analysis of safety.

Data on an interval or ordinal scale were analysed using the stratified Wilcoxon (mid) rank sum test, adjusting for each centre and parity. Analysis of variance was used to check for interaction between strata. P values correspond to two-sided tests and $P < 0.05$ was considered significant. Results are expressed as median (Q1/Q3) unless otherwise stated.

Results

A total of 104 women who requested extradural analgesia for labour were recruited (52 received ropivacaine, 52 bupivacaine). One patient was withdrawn because of technical difficulties (bupivacaine group). Thus we obtained data from 103 patients (ropivacaine 52, bupivacaine 51). Of these 103 women, only 102 received the entire first dose of study drug (one woman (ropivacaine) delivered after the test dose). An additional patient (bupivacaine) delivered before analgesia had occurred after the first dose. Thus 101 patients remained who satisfactorily received analgesia after the full first dose (ropivacaine 51, bupivacaine 50). For statistical analysis, 103

Table 1 Patient characteristics by treatment group (APT group) (mean (SD) [range]). No significant differences between groups

	Ropivacaine ($n = 52$)	Bupivacaine ($n = 51$)
Age (yr)	27.56 [18–42]	26.9 [18–39]
Height (cm)	161.9 (5.8) [150–178]	162.3 (6.5) [150–177]
Weight (kg)	74.4 (9.4) [56–104]	75.7 (10.2) [52–105]
Parity		
Primiparous	31	31
Multiparous	21	20

Table 2 Top-up doses (PD group) required in the two groups (median, Q1, Q3, range). * $P < 0.05$

Group	n	Median	Q1	Q3	Range
Ropivacaine	51	2	1	4	0–8
Bupivacaine	50	3*	1	4	0–7

patients were valid for safety analysis (APT) and 101 for efficacy analysis (PD). Another 17 women (ropivacaine eight, bupivacaine nine) discontinued the study prematurely (appendix). By far the commonest reason for withdrawal was delivery by Caesarean section.

The two groups were well matched in characteristics, parity and number of women who received one dose of pethidine before entering the study (eight ropivacaine, 10 bupivacaine) (table 1). Mean pre-anaesthetic i.v. infusion volumes were similar for each group: ropivacaine ($n = 52$) 653.85 (SD 233.02) (range 500–1000) ml; bupivacaine ($n = 51$) 676.47 (241.32) (500–1000) ml. There was no difference between the groups in the use of Entonox during labour (six ropivacaine, five bupivacaine).

MATERNAL EFFECTS

Top-ups

Eighteen percent of patients in the bupivacaine group required six or more top-ups compared with 7.8% in the ropivacaine group (table 2). The bupivacaine group required significantly more top-ups (3 *vs* 2) ($P < 0.05$) (Wilcoxon rank sum test) to achieve analgesia.

The mean total doses of study drug were: ropivacaine ($n = 52$) 37.69 (median 35.0) (Q1, Q3 25.0, 52.5) (range 5.0–95.0) ml; bupivacaine ($n = 51$) 43.04 (40.0) (25.0, 55.0) (15.0–85.0) ml.

Duration of treatment ranged from 0 to 864 min for the ropivacaine patients ($n = 52$) and from 11 to 710 min for the bupivacaine group ($n = 51$) (ns).

Pain relief

Time to onset of pain relief was 2–59 min (ropivacaine) ($n = 51$) and 1–64 min (bupivacaine) ($n = 50$) with a median onset time of 12 min (ropivacaine) and 10.5 min (bupivacaine) (ns).

Mean individual VAS scores assessed at each contraction after treatment began until the end of the first stage of labour were similar for each group: ropivacaine ($n = 51$) 20.94 (10.00–30.69) (0.61–50.00) mm; bupivacaine ($n = 50$) 15.59 (8.91–26.90) (0.75–62.68) mm. There was no difference between the treatment groups in duration of action of each top-up (table 3).

Table 3 Time between main or additional dose and first top-up dose, and times between supplementary top-ups (PD group) (median Q_1, Q_3, range). No significant differences between groups

Top-up No.		n	Duration of action (min) Median	Q_1	Q_3	Range
1	Ropivacaine	44	62.0	25.5	104.5	18–169
	Bupivacaine	49	56.0	23.0	84.0	12–164
2	Ropivacaine	29	94.0	82.0	119.0	29–249
	Bupivacaine	37	94.0	73.0	121.0	15–244
3	Ropivacaine	23	99.0	79.0	109.0	24–154
	Bupivacaine	28	89.5	66.5	123.0	29–172
4	Ropivacaine	15	94.0	74.0	120.0	23–208
	Bupivacaine	17	76.0	59.0	99.0	29–171
5	Ropivacaine	8	81.0	49.5	131.5	39–169
	Bupivacaine	12	90.0	71.0	124.0	44–174
6	Ropivacaine	4	42.5	14.5	72.0	14–74
	Bupivacaine	9	94.0	69.0	95.0	14–204
7	Ropivacaine	2	41.5	41.0	42.0	41–42
	Bupivacaine	2	82.0	54.0	110.0	54–110
8	Ropivacaine	1	138.0			

Table 4 Distribution of maximum motor block (PD group). No significant differences between groups

Group	Motor block: No motor block	Able to move knee	Able to move foot	Unable to move foot	Total
Ropivacaine	20	17	9	4	50
Bupivacaine	12	19	12	7	50
Total	32	36	21	11	100

Quality of analgesia was assessed the day after delivery in 92 patients and described by most as either excellent or good; 91.1% (ropivacaine), 95.4% (bupivacaine). No patient described pain relief as poor.

Upper segmental level of analgesia was assessed in 101 patients. The median level was T8 for both groups (range T3–T11 for ropivacaine ($n = 51$) and T2–T11 for bupivacaine ($n = 50$)). Motor block was assessed in 100 patients. The treatment groups did not differ in maximum motor block during the study period (table 4). However, 20 patients in the ropivacaine group failed to experience any motor weakness compared with 12 in the bupivacaine group (ns). The median duration for those with block was shorter in the ropivacaine ($n = 28$) 100.5 (Q1, Q3 65.5–180.0) min compared with the bupivacaine ($n = 32$) 161.0 (120.0–206.0) min group.

There was no difference between the groups in duration of the stages of labour (first stage: ropivacaine ($n = 45$) 257.0 (112.0–357.0) min, bupivacaine ($n = 44$) 231.5 (157.5–400.0) min; second stage: ropivacaine ($n = 45$) 55.0 (32.0–98.0) min, bupivacaine ($n = 44$) 66.5 (31.5–107.0) min). Patients who were delivered by Caesarean section were excluded from the analysis.

Table 5 Apgar score at 1 and 5 min, umbilical cord pH and Po_2 (kPa) at delivery (APT group) and neuroadaptive capacity (NAC) score at 2 (0.5) and 24 (2) h after delivery (PD group) (median, Q_1, Q_3, range). n = Number of babies. No significant differences between groups

	n	Ropivacaine	n	Bupivacaine
Apgar				
1	48	8.5 (7, 9) (5–10)	49	8.0 (7, 9) (1–10)
5	49	10.0 (9, 10) (8–10)	49	10.0 (9, 10) (4–10)
Umbilical vein				
pH	44	7.34 (7.29, 7.39) (7.06–7.46)	43	7.34 (7.30, 7.38) (7.19–7.48)
Po_2	32	25.00 (20, 29.55) (2.56–37.10)	29	24.30 (20.50, 29.80) (13.20–35.40)
Umbilical artery				
pH	43	7.25 (7.2, 7.32) (7.0–7.37)	41	7.25 (7.20, 7.30) (7.09–7.37)
Po_2	32	15.20 (10.9, 19.15) (6.00–32.90)	28	13.45 (10.35, 16.90) (3.30–27.90)
NAC score				
2 h	43	36 (35, 38) (32–39)	42	36 (36, 37) (29–40)
24 h	43	38 (37, 39) (33–40)	40	37 (36, 38) (30–39)

Women who received ropivacaine had an incidence of unassisted vaginal delivery (36 women) of 70.59 % compared with 52.0 % for the bupivacaine group (26 women) (ns). The number delivered by non-rotational low forceps in the bupivacaine group was 12 (24.00 %) compared with six (11.77 %) in the ropivacaine group (ns).

The remaining babies were delivered either by Caesarean section (five (9.8 %) ropivacaine, six (12 %) bupivacaine); vacuum extraction (three (5.9 %) ropivacaine; five (10.0 %) bupivacaine); or mid or high forceps (one (1.96 %) ropivacaine; one (2.00 %) bupivacaine (ns)).

FETAL EFFECTS

Birth weights for the groups were similar: ropivacaine ($n = 52$) 3410 g (Q1, Q3 3110, 3665 g) (range 2560–4650 g); bupivacaine ($n = 49$) 3400 g (3160, 3900 g) (2360–4470 g).

There was no difference between the groups in the condition of the neonate at delivery or at 24 h, as assessed by Apgar score, umbilical cord acid–base status and NAC scores, respectively (table 5).

Adverse events were classified as mild, moderate or severe. There were 66 maternal events (ropivacaine 37; bupivacaine 29). The majority (42) were mild (ropivacaine 23, bupivacaine 19). Mild events ranged from paraesthesia with extradural catheter insertion, cardiovascular alteration, poor/failed progression of labour, Caesarean section, postnatal depression and postpartum infective episodes such as cystitis or upper respiratory tract infection. The commonest single events were paraesthesia (seven cases) with insertion of the extradural catheter, and backache after delivery (seven cases). All patients either recovered spontaneously or had improved by the 2–3-week follow-up. Those women who delivered ultimately by Caesarean section (10) were classified as adverse events (nine maternal, one fetal).

Moderate events again included poor or failed progression of labour. In addition, events such as retrosternal pain, diarrhoea, tachycardia, nausea and vomiting, and vaginal and uterine haemorrhage were classified as moderate. One event was described as severe (uterine haemorrhage in the bupivacaine group). The patient had no long-term sequelae.

In the fetuses, 60 events were reported (31 ropivacaine, 29 bupivacaine): 50 % were described as mild (16 ropivacaine, 14 bupivacaine). With the exception of one patient (bupivacaine), these were cases of fetal bradycardia. Another 19 episodes of bradycardia were reported (12 moderate, seven severe).

Sixteen adverse events were described in the neonates (six ropivacaine, 10 bupivacaine). Similarly, the majority were mild (three ropivacaine, nine bupivacaine). The commonest event reported was jaundice (seven cases). All neonates recovered spontaneously.

Discussion

Ropivacaine should possess lower systemic toxicity than bupivacaine. In practice, although there is disparity between animal species in absolute cardiac and central nervous system toxicity [16, 17], Scott and colleagues [23] predicted less cardiovascular toxicity with ropivacaine than with bupivacaine in human volunteers after i.v. administration. This was deduced from analysis of the electrocardiograph.

To date, ropivacaine has been administered in clinical practice by several routes and over a range of concentrations (0.1–1 %). It has been shown to provide comparable analgesia–anaesthesia by the extradural route as bupivacaine for a variety of surgical procedures [20, 25], but uncertainty still exists over the relative depth of motor block with the two agents.

Our study suggested that 0.25 % ropivacaine and bupivacaine produced comparable analgesia in labour, in terms of onset, maximum level of sensory block and degree of patient satisfaction. Interestingly, bupivacaine-treated patients required more supplementary top-up doses to maintain effective analgesia.

Although there was no statistically significant difference in degree of motor block (as assessed by the Bromage score), there was a higher proportion of patients with no motor block in the ropivacaine-treated group. Similarly, and possibly linked, was the finding that a greater number of women in this group had spontaneous vaginal delivery. Unfortunately, one criticism of the Bromage score is that it incorporates an assessment of degree of spread of local anaesthetic in addition to depth of motor block. A more sensitive assessment of motor function would be isometric testing. This could be performed by assessment of the abdominal wall by a quantified electromyographic method and in the lower extremities by mechano-transducers [26].

Assessment of the effect of a local anaesthetic on the fetus is always difficult and relies largely on evaluation of the infant at delivery and over the ensuing hours. Traditionally, neonatal condition has been assessed with the Apgar scoring system and umbilical cord acid–base status.

To distinguish the effects of a drug on a neonate from those caused by *in utero* asphyxia requires more detailed assessment. Amiel Tison and colleagues developed the NAC score for this purpose [24]. It has been shown clinically to be a valid and sensitive test for evaluating neurobehavioural performance scores when comparing general with regional anaesthesia for Caesarean section [27]. Our study failed to demonstrate any difference between the groups in NAC scores or in the acid–base status of the infant at delivery.

We conclude that 0.25 % ropivacaine and 0.25 % bupivacaine produced comparable and effective maternal pain relief in labour without detriment to the fetus.

Absence of an early pre-emptive effect after thoracic extradural bupivacaine in thoracic surgery

J. L. AGUILAR, R. RINCÓN, V. DOMINGO, P. ESPACHS, M. J. PRECIADO AND F. VIDAL

Summary

We have determined if thoracic extradural block before surgical incision for thoracotomy produces pre-emptive analgesia. Using a double-blind, placebo-controlled, crossover design, 45 patients (ASA II–III) undergoing posterolateral thoracotomy for lung resection were randomized to one of three groups: group 1 received 0.5% bupivacaine and adrenaline 1/200000 (B+E) 8 ml through a thoracic extradural catheter (tip T3–T5) 30 min before skin incision and saline 8 ml 15 min after skin incision; group 2 received saline 8 ml extradurally before incision and B+E 8 ml after incision; group 3 received saline 8 ml extradurally before and after incision. General anaesthesia was induced and maintained with propofol, alfentanil and atracurium. The alfentanil infusion was stopped before chest closure and fentanyl 50 μg in saline 10 ml was given extradurally. Patient-controlled extradural analgesia (PCEA) was commenced with 0.125% bupivacaine, adrenaline 1/400000 and fentanyl 6 μg ml^{-1} (continuous rate of 2 ml h^{-1} and supplementary doses of 0.5 ml per 6 min). Visual analogue scale (VAS) scores (recorded at rest, on mobilization and after cough), verbal rating scale (VRS) (recorded at rest), number of successful PCEA demands and complications were measured during the first 48 h after operation. There was no significant difference between groups, either in PCEA requirements ($P > 0.21$) or in VAS scores (either at rest, during mobilization of the ipsilateral arm of surgery or after cough). No significant differences between groups were found in the VRS. Thoracic extradural block with bupivacaine did not produce an early preemptive effect after thoracotomy. (*Br. J. Anaesth.* 1996; **76**: 72–76)

Key words

Analgesia, pre-emptive. Pain, postoperative. Surgery, thoracic. Analgesic techniques, extradural. Anaesthetics local, bupivacaine.

In animals, tissue injury or brief afferent C-fibre conditioning stimuli results in increased excitability and expansion of the cutaneous receptive fields of flexor motor neurones and dorsal horn neurones [1, 2]. Central neurones may alter their structure or function as a result of past experience or injury [3]. Recordings from the spinal cord show that conduction between neurones is altered during noxious stimulation and may induce a hyperexcitable state, a phenomenon termed "wind-up" that may relate to a "pain memory", so that further stimuli are then said to potentiate the neural impulses and intensify the pain [4]. These experiments gave support to the concept of "pre-emptive analgesia."

However, the results of clinical studies are debatable. Conventional doses of oral NSAID appear to have no additional clinical benefit when given before compared with after surgery [5, 6]. Pre-emptive field block studies with local anaesthetics are inconclusive [7, 8]. I.v. opioids may confer some advantage when given pre-emptively [9]. Some studies on pre-emptive extradural block support the hypothesis, either with local anaesthetics [10] or opioids alone [11], using in both cases a lumbar approach. When opioids and local anaesthetics were combined, no pre-emptive effect was shown [12].

The aim of this study was to determine if extradural thoracic block with local anaesthetic before surgical incision had a pre-emptive effect on postoperative pain intensity in patients undergoing thoracotomy.

Patients and methods

The study was approved by the Institutional Review Board (IRB) and written informed consent was obtained from all patients. Forty-five patients, ASA II–III, undergoing posterolateral thoracotomy for lung resection were allocated randomly to one of three groups and studied prospectively in a double-blind, placebo-controlled, crossover design.

All patients were familiarized with the following pain intensity measurements: 10-cm linear visual analogue scale (VAS); verbal rating scale (VRS) described as: no pain, slight, moderate, strong, intense and unbearable; and patient-controlled extradural analgesia (PCEA) pump management.

Preoperative investigations in all patients included arterial blood-gas measurements, pulmonary function tests, haematology, coagulation, biochemical

screening and thoracic radiology. Exclusion criteria were: renal disease (creatinine > 106 μmol litre^{-1}), hepatic disease (bilirubin > 20 μmol litre^{-1}), congestive heart failure, atrioventricular heart block, epilepsy, alcoholism, hypovolaemia, age less than 18 or more than 76 yr, metrizamide allergy, a history of chronic pain or regular intake of analgesic drugs, a psychiatric history, any contraindication to regional anaesthesia and failure to comprehend PCEA or any of the pain intensity scales.

A table of random numbers was used to generate a randomization schedule to which each patient would be assigned upon entry into the trial. An envelope containing the group assignment (and the order of bupivacaine and saline infusions) was prepared, sealed and numbered for each patient. On the morning of surgery, one of the investigators opened the envelope and prepared two identical syringes that were labelled for pre-incisional and post-incisional infusions. This investigator had no further involvement with the study. All patients and personnel involved in patient management and data collection were unaware of the group to which the patient had been allocated. Although the anaesthetist in charge of the case also was unaware of the patient's group, he had ready access to this information in the event of an emergency.

The day before surgery, an extradural thoracic catheter was inserted and its tip placed at T3–5 using an 18-gauge Tuohy needle [13]. The position of the catheter tip was checked using an image intensifier by administration of metrizamide.

Two different extradural solutions were used: 0.5 % bupivacaine with adrenaline 5 μg ml^{-1} (B) and saline solution (S), in a total volume of 8 ml for each dose. The first extradural dose was administered 30 min before surgical incision and the second 15 min after.

Lorazepam 1 mg was administered orally on the night before surgery and 1 h before anaesthesia. Ringer's lactate solution 1 litre was administered i.v. and a radial artery cannula inserted. EEG, non-invasive arterial pressure, Sp_{O_2} and expired carbon dioxide were monitored. Anaesthesia was induced with propofol 2 mg kg^{-1}, alfentanil 15 μg kg^{-1} and atracurium 0.5 mg kg^{-1} to facilitate tracheal intubation with a double-lumen tracheal tube. Anaesthesia was maintained with a continuous infusion of propofol 6 mg kg^{-1} h^{-1}, alfentanil 1 μg kg^{-1} min^{-1} and atracurium 0.3 mg kg^{-1} h^{-1}. Alfentanil 5 μg kg^{-1} was given every 5 min if arterial pressure or heart rate was 25 % or more than baseline. The lungs were ventilated with 100 % oxygen. The alfentanil infusion was stopped before chest closure. At the end of operation residual neuromuscular block was antagonized with neostigmine, and atropine and fentanyl 50 μg in 10 ml of saline solution were given extradurally. The trachea was extubated immediately after surgery and the patient transferred to the recovery room.

In the recovery room, an extradural infusion of 0.125 % bupivacaine with adrenaline 1/400000 and fentanyl 6 μg ml^{-1} was started using a PCEA pump system (Pharmacia Deltec). A continuous rate of 2 ml h^{-1} and supplementary boluses of 0.5 ml, with a 6-min lockout interval, were given during the first 48 h after operation. PCEA was then stopped and restarted if analgesia was inadequate. The following analgesic regimen was then commenced: tramadol 1 mg kg^{-1} i.v. every 6 h alternated with metamizol 30 mg kg^{-1} i.v. every 6 h for 3 days. When i.v. medication was impractical, the same analgesic regimen was maintained by the oral route, with consequent reduction in dosage. The thoracic extradural catheter was removed when oral administration began.

Pain scores at rest, during abduction of the ipsilateral arm and after cough were recorded on a 10-cm linear VAS at 1, 3, 7, 11, 19 and 43 h after surgery. Pain scores at rest were also determined at the same times on a VRS. Total successful PCEA demands were recorded at 18 and 48 h after operation. Arterial blood-gas analysis was performed at 1, 3, 7, 19 and 43 h after operation. Side effects (nausea, vomiting, pruritus, respiratory depression and hypotension) were recorded.

DATA ANALYSIS

We estimated the sample size required for a test assuming that postoperative pain would be less intense in group 1 (extradural bupivacaine before surgical incision) than in the two other groups. Using as a principal variable the VAS for postoperative pain and considering a difference of ±2 cm as clinically significant, we calculated the sample size required. Considering a type I α error of 0.05 and a type II β error of 0.1, assuming a minimized, although not fully absent, type II β error, the sample size was calculated as 15 patients in each group.

Eight patients were withdrawn from the study because of: inadequate pain relief in spite of PCEA as a result of ipsilateral shoulder pain ($n = 5$; two in group 1, two in group 2 and one in group 3); loss of the extradural catheter before the end of the study ($n = 1$; group 2); or incomplete data collection ($n = 2$; one in group 1 and one in group 2). The patients withdrawn were replaced until 45 patients had completed the study.

Qualitative data (sex, type of intervention and verbal categoric scale) were assessed by a chi-square test with Yates' correction, when necessary. Quantitative data were examined with analysis of variance according to Scheffé's procedure. Differences between groups were tested with the two-tailed Student's test. The Kruskall–Wallis test was used for non-parametric data. Values of $P < 0.05$ were considered significant.

Results

There were no significant differences between groups in age, weight, height, sex, type of surgical procedure or duration of surgery (table 1).

The total doses of alfentanil, propofol and atracurium, and the bolus of alfentanil received in the intraoperative period by each patient did not differ significantly between the groups (table 1).

There were no differences in VAS scores either at

rest (fig. 1), during mobilization of the ipsilateral arm of surgery (fig. 2) or after cough (fig. 3). There were no significant differences between groups in VRS (table 2) or in requirements for PCEA (table 3).

Arterial blood-gas analyses showed no significant differences (table 4) between groups.

No complications or adverse effects were observed in any of the patients.

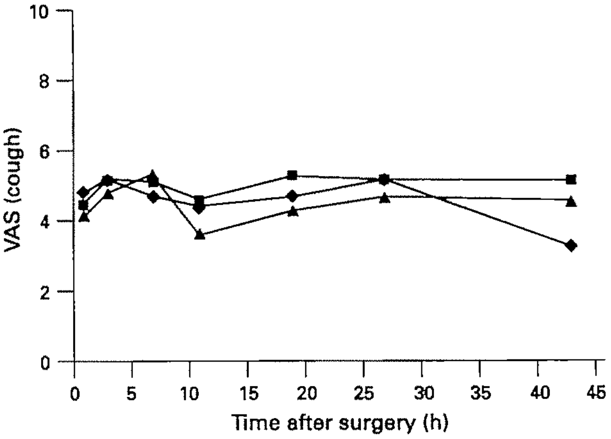

Figure 3 VAS pain intensity after coughing throughout the study in the bupivacaine–saline (■), saline–bupivacaine (▲) and saline–saline (◆) groups.

Discussion

We found no significant differences in pain scores at rest, during mobilization of the ipsilateral arm or after cough between patients with pre-incisional (30 min) and post-incisional (15 min) administration of a thoracic extradural with 0.5% bupivacaine using the suggested design for studies of pre-emptive analgesia [14]. There may be several explanations for the difference between our findings and those of previous studies. Although central sensitization may contribute to postoperative pain in humans, surgical trauma differs from the conditioning stimuli applied in experimental studies in several aspects. Contrary to a well-localized thermal or chemical injury, or brief C-afferent stimulation, the afferent input to the CNS during surgery is extensive, with mixed cutaneous, muscular and visceral components. In thoracic surgery there are several noxious peri-operative events, such as rib retractor placement, insertion of chest drains, intercostal nerve damage, rib fractures and stripping of the periosteum. Surgery may be considered as an uncontrolled prolonged stimulus involving generation of afferent stimuli from somatic and visceral fibres and may not, therefore, be directly comparable with experimental models. Moreover, this afferent input is maintained while the inflammatory surgical response lasts.

Our findings contrast with those of Katz and

colleagues [11], although we used similar administration times. They used the lumbar extradural route and gave fentanyl 4 µg kg^{-1}. We used the thoracic approach and gave 0.5 % bupivacaine 8 ml.

Our negative results could be caused by administration of too small a dose of extradural bupivacaine which may not be sufficient to provide good afferent block [15]. Furthermore, the block was instituted 30 min before surgery which might not be long enough for optimal pre-emptive analgesia, although a clinically effective block would have been achieved.

Katz and colleagues used i.v. PCA with morphine while we used PCEA. They found a significantly increased analgesic effect only at 6 h and reduced morphine consumption between 12 and 24 h after surgery in the treated group [11] (pain scores and postoperative morphine consumption were reduced only at one of five assessments). Total morphine consumption however was almost identical in both groups. The pre-emptive study group was older and included more females than the control group, both of which factors may result in less pain and opioid consumption [16].

An explanation for our failure to show a pre-emptive effect could be that central sensitization was induced equally in the three groups, as a result of insufficient afferent block. Conventional extradural block may not provide total C-afferent block and the vagi and phrenic nerves are unaffected [17]. Extradural block in our study was obtained with a potent local anaesthetic (bupivacaine 5 mg ml^{-1} (8 ml)) suitable for surgical anaesthesia, but the degree of afferent block was not established with any objective method.

Pre-emptive, balanced (combining NSAID, opioids, local anaesthetics and other drugs) and prolonged analgesia throughout the inflammatory response has been suggested as the only way to induce a significant effect on pain intensity. A single extradural dose cannot be expected to have prolonged effects; a secondary neuroplastic response may be expected when the block wears off [18].

C-afferent activity may be generated not only during surgery, but also in the postoperative period, partly as a result of persistent inflammation and hyperalgesia at the wound site. This activity may be sufficient to produce central sensitization and no information is available on the optimal duration of afferent block to prevent alterations in dorsal horn neurones. In our design, central sensitization may have occurred in the pre-emptive study group (group 1) during the postoperative period when the concentration of bupivacaine used for continuous extradural infusion was small. It may be that the windup process outlasts the effect of bupivacaine. What we thought was pre-emptive analgesia may merely have been pre-incisional. The prevention of pain must begin before operation and then continue during and after operation [19].

It has been suggested that administration of opioids as premedication or during induction and maintenance of anaesthesia may attenuate central hyperactivity and consequently confound postoperative assessments of pain and analgesic requirements [9, 11, 20]. Morphine has been shown to prevent the establishment of central sensitization [21] in rats. In a recent study [9], morphine 10 mg i.v. was more effective when administered before compared with after hysterectomy. In our study, however, it is remarkable that although the number of doses of alfentanil given during the intraoperative period was greater in group 3 (S-S), there were no significant differences in postoperative pain assessments between groups. Clinical studies of pre- *vs* postoperative opioids [9, 11] seem to confirm the theoretical importance of pre-emptive analgesia [22], but only very minor and shortlasting advantageous effects have been documented.

The potential pre-emptive effect of an extradural test dose with local anaesthetic is also controversial. One study found no significant differences in pain and opioid requirements after identical pre- or postoperative extradural block with bupivacaine in patients undergoing abdominal hysterectomy [23], while a recent study [10] during lower abdominal surgery showed a reduction in the required dose of morphine and McGill pain questionnaire, although VAS did not differ significantly. In an earlier study, patients undergoing colonic surgery given either an extradural dose of bupivacaine 7 ml (7.5 mg $\mathrm{ml^{-1}}$) with morphine 2 mg before or after surgery, followed by continuous extradural bupivacaine 0.25 mg $\mathrm{ml^{-1}}$ (4 ml $\mathrm{h^{-1}}$ for 72 h) showed no significant differences in pain scores at rest or during mobilization, or in requests for additional morphine [12].

It may be suggested that wound hyperalgesia is a more sensitive measure of pain reduction. Hyperalgesia (increased sensitivity and extended sensory fields) may be the earliest and most sensitive manifestation of inadequate antinociceptive control and could be investigated in future studies by measuring sensory and pain cutaneous thresholds. However, the clinical relevance of these measures is not great. A recent study of fentanyl or ketamine i.v. [24] found no statistically significant changes in spontaneous incisional or movement-associated pain compared with the control group, although the intensity of pain to suprathreshold pressure on the wound was decreased in both treatment groups compared with the control group.

Prilocaine 3% is superior to a mixture of bupivacaine and lignocaine for peribulbar anaesthesia

U. R. DÖPFMER, D. G. MALONEY, P. A. GAYNOR, R. M. H. RATCLIFFE AND S. DÖPFMER

Summary

We have compared motor block of the extraocular muscles produced by injections of 3% prilocaine and a mixture of equal parts of 2% lignocaine and 0.75% bupivacaine into the medial compartment of the orbit. A volume of 8 ml was used initially, and a vasoconstrictor and hyaluronidase were added to both solutions. Ninety patients undergoing cataract surgery were allocated randomly to one of two groups in a double-blind study. Eight minutes after block insertion, the median ocular movement score in the prilocaine group was 1 and in the lignocaine–bupivacaine group 3. This difference was statistically significant ($P = 0.016$). Twenty of the patients who received prilocaine and 29 of the patients who received the lignocaine–bupivacaine mixture required an additional inferotemporal injection. This difference was not statistically significant ($P = 0.094$). (*Br. J. Anaesth.* 1996; **76**: 77–80)

Key words

Anaesthetic techniques, regional, peribulbar. Anaesthetics local, prilocaine. Anaesthetics local, bupivacaine. Anaesthetics local, lignocaine.

In our opinion, regional anaesthesia is the technique of choice for the vast majority of patients undergoing cataract surgery. Peribulbar anaesthesia seems to be safer than injections inside the extraocular muscle cone, especially when non-ophthalmologists perform the block [1,2].

Many modifications of the peribulbar technique have been described since the original report of Davis [3]. These include a variety of points of needle entry, direction and depth of needle insertion and of number of injections made [4].

A mixture of bupivacaine and lignocaine is the local anaesthetic used most frequently. Hyaluronidase and adrenaline are commonly added in varying concentrations to this mixture. Prilocaine has been used successfully for regional ocular anaesthesia [5, 6]. We are not aware of any formal comparison of prilocaine and a mixture of bupivacaine and lignocaine for peribulbar anaesthesia. In the UK preservative-free prilocaine in a concentration of 3% is available only in combination with felypressin. We added hyaluronidase to this solution and compared it with a combination of lignocaine, bupivacaine, hyaluronidase and adrenaline using a single injection into the medial compartment of the orbit.

Patients and methods

The local medical Ethics Committee gave approval for the study, and 90 patients presenting for cataract surgery under local anaesthesia gave informed consent. The sample size was determined on the basis of power calculation [7]. This study had a 95% chance of detecting a statistically significant (at the 5% level) true difference of 2 points for the sums of the eye movement scores.

Patients were allocated randomly to group 1 or 2. Group 1 received a mixture of equal volumes of 2% lignocaine and 0.75% bupivacaine, with adrenaline 5 $\mu g\ ml^{-1}$ and hyaluronidase 75 u. ml^{-1} (the mixture group). Group 2 received 3% prilocaine, with felypressin 0.03 u. ml^{-1} (Citanest with Octapressin, Astra) and hyaluronidase 75 u. ml^{-1} (the prilocaine group).

Randomization was performed in blocks of 10, using statistical tables for permutated blocks. The block size was not known by the investigators. Allocation was undertaken using sealed envelopes, which were not handed over to the clinician performing the blocks, but to an anaesthetist not involved in the trial, who then drew up the local anaesthetic mixture and handed the unlabelled syringe to the investigator.

All patients were assessed before operation; they were not premedicated and not fasted. On arrival in the anaesthetic room analgesia of the conjunctiva and cornea was provided by administering 2–3 drops of 1% amethocaine topically, twice within 2 min. In the interval between these two doses a vein was cannulated and arterial pressure measured with an automated oscillometer; monitoring of arterial oxygen saturation and the ECG was commenced. Approximately 1 min after the last dose of amethocaine eye drops, injection into the medial compartment of the orbit was carried out. A 25-gauge, 25-mm hypodermic needle was inserted just medial to the caruncle. The needle was introduced along the medial wall of the orbit to a depth of 20–25 mm. The sharp bevel was facing the globe. The direction of

insertion was almost perpendicular to the frontal and parallel to the sagittal plane; the eye was in the neutral position. After gentle negative aspiration, 8 ml of solution was injected over 30–40 s. A similar technique has been described by Brahma and co-workers [6]. Manual massage and gentle compression of the eyeball was performed for the first 2 min after this injection. Between scoring, a Honan balloon inflated to a pressure of 30 mm Hg was applied.

Globe movement was scored for each direction of gaze, as shown in table 1 [6]. The maximum score for each direction at any time was 3 points, the maximum sum 12 points. The scoring system for eyelid movements is also shown in table 1. Globe and eyelid movements were assessed at 2, 4, 6 and 8 min and thereafter every 2 min up to 16 min, if the block was considered inadequate for surgery 8 min after the first injection. If the block was still not sufficient at 10 min, another injection of the same drug was given.

Supplementary injections were given by the transconjunctival route with needle insertion at the lower margin of the orbit at the junction of the lateral and middle third. The needle was directed along the floor of the orbit to a depth of 20–25 mm; 2–5 ml of the solution used previously was injected after a negative aspiration test. The time when the operation started was noted.

Complications during or after injection were noted, and patients were asked after operation if they experienced any pain during surgery or while the block was inserted. Predefined summary measures [8] were the difference in median scores after 8 min, and the time needed to reach adequate block to start the operation. Data were analysed by Wilcoxon rank sum test. The need for top-up injections, the number of patients who reached an ocular movement score of 0 or 1 and complications were compared using the chi-square or Fisher's exact test, as appropriate.

Results

Patient characteristics in the two groups were similar (table 2).

Table 2 Baseline characters of patients (mean (SD or range) or number)

	Group 1	Group 2
n	46	44
Sex (M/F)	18/28	16/28
Age (yr)	75 (44–96)	76 (37–92)
Axial length (mm)	22.8 (1.2)	22.8 (1.0)

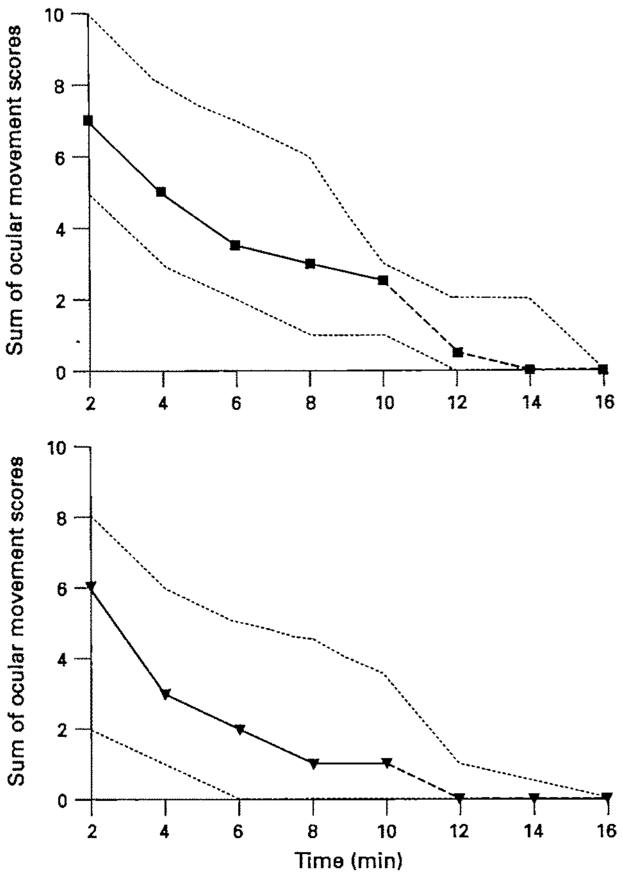

Figure 1 Sum of ocular movement scores (medians and interquartile ranges) over time in the lignocaine–bupivacaine (top) and prilocaine (bottom) groups. Required top-up injections were given at 10 min.

Complications during or after injection did not differ between the two groups (Fisher's exact test, $P = 0.714$). Seventeen patients in each group reported mild discomfort on inserting the block; significant conjunctival chemosis occurred in two patients in the mixture group, and four patients in the prilocaine group. This did not interfere with surgery. Subcutaneous haematoma formation occurred in three patients (two and one, respectively). Complications of a more serious nature were not noted. Only four patients reported intraoperative pain (three in the mixture group and one in the prilocaine group). One patient required additional topical anaesthesia with amethocaine drops, while the other three patients showed no signs of intraoperative distress, but reported minor pain on direct questioning immediately after operation. Eyelid movement was always blocked satisfactorily at 8 min. There was no significant difference in scores between the two groups ($P = 0.294$).

At 8 min the sum of the ocular movement scores was significantly lower in the prilocaine group (Wilcoxon rank sum test, P (two-sided) $= 0.0163$). The sums of the ocular movement scores over time are shown in figure 1. Ocular movement scores 8 min after injection are shown in figure 2.

Twelve patients in the mixture group and 27 patients in the prilocaine group had an ocular movement core of 0 or 1, 8 min after the medial injection (chi-square $= 11.4$, P (two-sided) < 0.001).

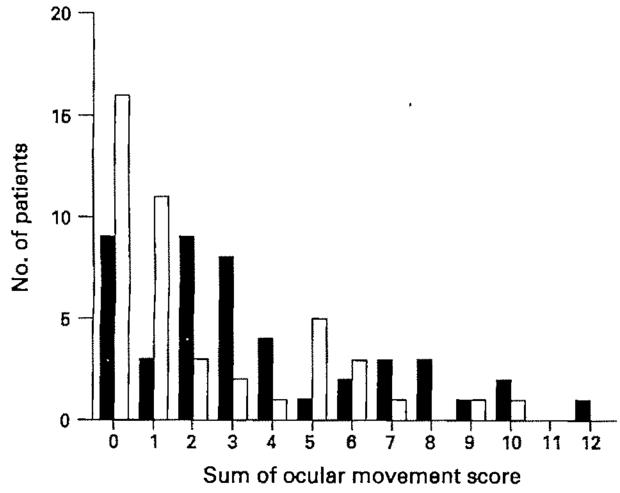

Figure 2 Distribution of the sums of the ocular movement scores 8 min after injection, for the lignocaine–bupivacaine (■) and the prilocaine (□) groups.

The median time at which the block was considered to be sufficient to start the operation was 12 min in the mixture group and 10 min in the prilocaine group (*P* (two-sided) = 0.091). Twenty-nine (63 %) patients in the mixture group and 20 (45.5 %) in the prilocaine group needed supplementary injections because the block was still not adequate at 10 min, a difference which did not reach statistical significance (chi-square = 2.81, *P* (two-sided) = 0.094). The insertion of top-up injections was completely pain-free in all patients.

Discussion

We have shown that prilocaine provided better ocular akinesia within the first 10 min after block insertion than a lignocaine–bupivacaine mixture when used for peribulbar block in combination with a vasopressor and hyaluronidase.

We deliberately chose a single injection into the medial compartment, as a high success rate has been reported previously for this technique [6]. Furthermore, we considered a single injection technique to be more likely to reveal an inherent difference between the spread of the agents throughout the orbit. The medial entry site for the needle was chosen because it is our experience that this injection causes much less discomfort than the inferotemporal approach, no matter whether the latter is performed through a transdermal or a transconjunctival route.

Our re-block rate in both groups was higher than in previously reported studies [6, 9–11], perhaps because we strived for almost complete ocular akinesia as the majority of patients were operated on without the use of holding stitches to avoid post-operative astigmatism. Despite this, we still advocate the technique described. The only alteration that we have made for routine cases is that assessment of the need for additional injections is made 6 min after the initial block. By that time analgesia of the inferotemporal part of the globe and orbit is well established, and an additional injection at this site is completely pain-free and abolishes residual downward and lateral eye movement within a short time.

Many scoring systems have been used for ocular range of movement [6, 12–14]. All of these are subjective, and commonly only sum scores incorporating all directions of gaze are reported, although it is obvious that major movement in only one direction is more disruptive to surgery than minor movement in two or more directions. Therefore, usually sum scores and re-block rates are reported simultaneously. An accurate, objective method of measuring eye movement that is easily performed in the anaesthetic room would greatly facilitate research in this field.

We did not study the duration of anaesthesia and analgesia provided by prilocaine, but patients never experienced pain towards the end of surgery, despite delays of up to 1.5 h in the operating programme.

We chose to add a large dose of hyaluronidase to the local analgesic solution as we wished to take advantage of any possible effects promoting spread. There is conflicting evidence on whether or not hyaluronidase improves the onset time or final akinesia achieved in double injection peribulbar blocks with lignocaine and bupivacaine [11, 13, 15]. Further studies are needed to determine if hyaluronidase is a useful addition to prilocaine when used for the technique described.

It would also be interesting to determine if the lignocaine–bupivacaine mixture would eventually have reached the same degree of extraocular muscle block had no further injections been given after 10 min. This study did not establish whether there is purely a difference in time of onset, or a true difference in maximum motor block, achieved with the two solutions.

Haemodynamic effects of moderate normovolaemic haemodilution in conscious and anaesthetized patients

P. Biboulet, X. Capdevila, D. Benetreau, P. Aubas, F. d'Athis and J. du Cailar

Summary

We have assessed the haemodynamic effects of moderate normovolaemic haemodilution in ASA I patients, either conscious or during enflurane–fentanyl anaesthesia (10 patients in each group). Cardiac index (CI), stroke index (SI) and ejection fraction (EF) were measured by transthoracic electrical bioimpedance and, in the anaesthesia group, arterial and central venous blood samples were obtained to assess oxygen delivery ($D\mathrm{O}_2$), oxygen consumption ($\dot{V}\mathrm{O}_2$) and oxygen extraction ratio (O_2ER). In conscious patients, heart rate (HR) remained unchanged as SI, EF and CI increased. When haemodilution was performed during anaesthesia, CI remained stable in spite of a slight increase in SI, as HR decreased. This produced a reduction in $D\mathrm{O}_2$ which was compensated for by an increase in O_2ER, allowing maintenance of $\dot{V}\mathrm{O}_2$ without alteration in blood lactate concentration. (*Br. J. Anaesth.* 1996; **76**: 81–84)

Key words

Blood, haemodilution. Measurement techniques, transthoracic electrical impedance. Cardiovascular system, effects.

Preoperative acute isovolaemic haemodilution is commonly used to avoid the adverse consequences of homologous blood transfusion [1]. Moderate haemodilution, defined by a decrease in packed cell volume (PCV) of approximately 30% [2] has been shown to be relatively safe, as the decrease in arterial oxygen content is compensated for by an increase in cardiac output, maintaining oxygen delivery. The increase in cardiac output results from an increase in stroke volume rather than heart rate [3–6] and occurs in response to a decrease in blood viscosity and increased myocardial contractility [7, 8]. The reduction in blood viscosity plays a fundamental role by decreasing myocardial afterload [4] and increasing venous return [9]. In order to explain the increased myocardial contractility, an increase in sympathetic tone has been suggested [10], mediated by baroreceptors and chemoreceptors [11]. In contrast with these data obtained from studies performed under light anaesthesia [3, 5, 6], an increase in cardiac output during haemodilution does not occur during neuroleptanalgesia [12] or during enflurane–nitrous oxide anaesthesia [13]. As most anaesthetic agents decrease myocardial contractility and venous return, they might attenuate the haemodynamic response to acute haemodilution. However, these two studies were performed in elderly patients [12] or in patients with cardiovascular disease, or both [13], factors which may compromise the cardiovascular changes occurring during haemodilution.

The aim of this study was to assess the haemodynamic changes after normovolaemic haemodilution in ASA I patients, either conscious or under anaesthesia, in order to examine the effect of anaesthetic agents on the cardiovascular response.

Patients and methods

The study was approved by the local Ethics Committee and informed consent was obtained from each patient.

CONSCIOUS PATIENTS

We studied 10 consecutive ASA I patients, aged 23–48 yr, undergoing orthopaedic surgery. Haemodilution was performed the day before surgery in unpremedicated patients. The blood volume to be withdrawn to achieve a PCV of about 30% was calculated from basal PCV levels using a chart. Blood was collected into standard citrate–phosphate–glucose blood storage bags and replaced simultaneously by i.v. administration of an equal volume of dextran 60 (Hemodex). The characteristics of this colloid are: 6% concentration, molecular weight of approximately 60000 Da and oncotic pressure 7.46 kPa. The likelihood of an anaphylactic reaction was reduced by hapten inhibition with dextran 1000 (Promit) 3 g.

PCV was measured using the micromethod (Compur M 1101, Compur Electronic GmbH, Munich, Germany) before, during and 5 min after haemodilution. Heart rate (HR) was measured from an electrocardiogram and mean arterial pressure (MAP) using an automated method (Trend BP 5000, Colin Electronics Co. Ltd, Japan). Cardiac index (CI), stroke volume index (SI) and left ventricular

ejection fraction (EF) were measured or calculated non-invasively by transthoracic electrical bio-impedence (TEB) using the Bomed NCCOM3 with software version R-7 (Bomed Medical Manufacturing Ltd, Irvine, CA, USA). For TEB data, three recordings were averaged over the time taken to record arterial pressure. Haemodynamic variables were measured at rest, before haemodilution (T0) and 5 min after (T1).

ANAESTHETIZED PATIENTS

We studied 10 consecutive ASA I patients, aged 18–55 yr, undergoing major elective orthopaedic surgery with haemodilution. Patients received midazolam 0.1 mg kg^{-1} i.m. as premedication. Anaesthesia was induced, without preloading, with fentanyl 5 μg kg^{-1}, thiopentone 5 mg kg^{-1} and vecuronium 0.1 mg kg^{-1}, and maintained with fentanyl 0.08 μg kg^{-1} min^{-1} and 0.8% enflurane. After tracheal intubation, patients' lungs were ventilated with 50% nitrous oxide in oxygen and tidal volume was adjusted to maintain end-tidal carbon dioxide values of 4.5 kPa.

Cannulae were inserted in a radial artery and the right internal jugular vein. Normovolaemic haemodilution was performed as described previously, after induction and insertion of the cannulae. PCV and haemodynamic variables (HR, MAP, CI; SI and EF) were measured using the same method as in the conscious group. Additionally, central venous pressure was measured and arterial and central venous blood samples were obtained to measure arterial oxygen content (Ca_{O_2}), central venous oxygen content (Ccv_{O_2}) and arterial blood lactate concentration. Blood samples were analysed immediately using an automated system for blood gases (Radiometer ABL 330, Radiometer CO, Copenhagen, Denmark). Oxygen saturation, haemoglobin (Radiometer OSM2, Radiometer CO, Copenhagen, Denmark) and blood lactate concentrations (enzymatic method) were measured also. Oxygen delivery (Do_2), oxygen consumption ($\dot{V}o_2$) and oxygen extraction ratio (O_2ER) were calculated with standard formulae using central venous data instead of mixed venous measurements. Haemodynamic measurements were performed and blood samples obtained just before haemodilution (T0) and 5 min after (T1).

Table 1 Patient characteristics (mean (range or SD))

	Age (yr)	Height (m)	Weight (kg)
Conscious patients	38 (23–48)	1.74 (0.11)	69 (14)
Anaesthetized patients	36 (18–55)	1.71 (0.07)	69 (11)

STATISTICS

Data are expressed as mean (SD). Statistical analysis was performed using the Wilcoxon test. The level of significance was defined as $P < 0.05$.

Results

CONSCIOUS PATIENTS

Haemodilution was performed in three women and seven men (table 1). The mean volume of blood withdrawn was 1058 (261) ml over a period of 49 (16) min. PCV decreased from 41 (4) % at T0 to 30 (1) % at T1 ($P < 0.05$). After haemodilution, SI, EF and CI increased as HR and MAP remained unchanged (table 2).

ANAESTHETIZED PATIENTS

Haemodilution was performed in three women and seven men (table 1). The mean time from induction of anaesthesia to haemodilution (T0) was 54 (5.8) min. The mean volume of blood withdrawn was 926 (294) ml over 38 (10) min. PCV decreased from 38 (3)% at T0 to 29 (2)% at T1 ($P < 0.05$), corresponding to a decrease in arterial haemoglobin from 12.4 (1) g 100 ml^{-1} to 9.5 (0.6) g 100 ml^{-1} ($P <$ 0.05). After normovolaemic haemodilution, MAP and HR decreased, SI and EF increased, as CI and CVP remained unchanged (table 3). Ca_{O_2} and Do_2 decreased considerably, central venous saturation (Scv_{O_2}) decreased while $\dot{V}o_2$ did not change significantly and O_2ER increased. Blood lactate concentrations remained unchanged and Pa_{CO_2} remained stable (table 4).

Discussion

We have shown that the haemodynamic effects of moderate normovolaemic haemodilution were different in conscious and anaesthetized ASA I patients. When haemodilution was performed on conscious patients, the classic haemodynamic response described previously [3–6] was observed. The significant increase in CI resulted from an increase in SI as HR remained unchanged; the increase in SI was related to the increase in EF. Conversely, when haemodilution was performed under anaesthesia, CI remained stable, in spite of a slight increase in SI, as HR decreased. This produced a reduction in Do_2 compensated for by an increase in O_2ER which induced a decrease in $ScvO_2$. This metabolic response allows maintenance of $\dot{V}o_2$ without alteration in blood lactate concentration, evidence of adequate global tissular oxygenation.

In this study, we used the non-invasive bio-

impedance method [14], the accuracy of which has been controversial. In critically ill patients with water and electrolyte disorders, measurement of CI by TEB lacks precision [15–17] but the technique is accurate in normal subjects and in high risk surgical patients [18–21]. Measurement of EF by the TEB method has been validated also [22]. Changes in PCV have little influence on the calculation of CI by the Sramek formula used by the Bomed NCCOM3 [17, 23]. Blood obtained from the superior vena cava was used for measurement of venous oxygen saturation. However, adequate correlation between central venous and mixed venous oxygen saturation [24–26] has been questioned recently in critically ill patients [27–29].

Our findings agree with the study of Van der Linden and colleagues where CI remained stable, in spite of a slight increase in SI, as HR decreased when haemodilution was performed during enflurane–nitrous oxide anaesthesia [13]. This results in a significant decrease in Do_2; $\dot{V}o_2$ was maintained by an increase in O_2ER. The smaller increase in SI and the decrease in HR seem to be related to the inotropic and bradycardiac effects of the anaesthetic agents. Enflurane is known to have both a depressant effect on the myocardium [30, 31] and on cardiac conduction [32]. Vecuronium and thiopentone with or without fentanyl have been associated with significant bradycardia [33]. Cases where CI has failed to increase during moderate haemodilution have been described also during neuroleptanalgesia [12].

On the other hand, those studies which reported an increase in CI with maintenance of Do_2 during haemodilution were conducted in conscious patients [34] or using low concentrations of anaesthetic agents [3, 5, 6].

The metabolic repercussions of this inadequate haemodynamic response to acute anaemia when haemodilution is performed under anaesthesia are difficult to determine. It is unlikely that a global measure such as Do_2, $\dot{V}o_2$ or blood lactate concentration can predict adequately the responses of specific tissues to decreased oxygen delivery [35]. For example, haemodilution improves the microcirculation with more homogeneous distribution of capillary flow resulting in improvement in local oxygen supply [1]. Additionally, $\dot{V}o_2$ decreases during general anaesthesia. The myocardium is one of the principal organs at risk during haemodilution as O_2ER exceeds 50%; nevertheless, haemodilution is tolerated well in patients with coronary disease [4, 36, 37]. However, if oxygen demand increases, the magnitude of haemodilution may be inappropriate, which explains the higher incidence of postoperative cardiac ischaemia in atherosclerotic patients when PCV is less than 29% [38]. The major problem is during the recovery period when oxygen demand increases. A critical level of haemodilution is therefore difficult to define, particularly in patients with coronary artery disease [35, 39, 40].

In summary, we found that haemodynamic response to moderate normovolaemic haemodilution was impaired in ASA I patients during enflurane–fentanyl anaesthesia. $\dot{V}o_2$ was maintained by a corresponding increase in O_2ER. In high-risk patients this metabolic adaptation may be inadequate, resulting in a $\dot{V}o_2$ which is dependent on oxygen supply thus leading to local tissue ischaemia.

Analysis of ethanol in expired air during low-flow isoflurane anaesthesia

J. OLSSON AND R. G. HAHN

Summary

Monitoring of ethanol concentration in expired air is a method for assessing fluid absorption during transurethral prostatic surgery and endometrial resection, but the validity of this technique has not been studied in low-flow ventilation systems. For this purpose, we have compared the concentration–time profiles of ethanol in expired gas and in venous blood during an i.v. infusion of 0.4 g kg^{-1} of ethanol over 30 min in 10 women during isoflurane anaesthesia and in the awake state. Anaesthesia increased the ethanol concentration in expired gas by 13% and in venous blood by 34%. The expired gas–blood difference during infusion was abolished, and the central volume of distribution for ethanol was reduced from 20.9 to 8.6 litre, on average. We conclude that breath sampling during low-flow isoflurane anaesthesia reflects an alcohol load well, but that a change in ethanol disposition makes the values slightly higher than in the awake state. (*Br. J. Anaesth.* 1996; **76**: 85–89)

Key words

Anaesthetics volatile, isoflurane. Ethanol. Pharmacokinetics.

Measurement of ethanol in expired gas is performed most frequently in awake subjects who are suspected of driving offences in relation to drinking alcohol. In recent years, ethanol analysis in expired gas has been used as a marker of fluid absorption during transurethral resection of the prostate [1,2] and transcervical resection of the endometrium [3,4]. Ethanol monitoring was developed originally for spontaneously breathing patients under regional anaesthesia, but it has also been used under general anaesthesia [5,6]. However, atelectasis and hypothermia would be expected to give lower values for ethanol in the breath [7] while tracheal intubation may increase them by reducing the reabsorption of ethanol in the oral cavity during expiration [6].

The aim of the present study was to evaluate the validity of measurement of ethanol in expired gas during isoflurane anaesthesia using a low-flow breathing system. This was done by comparing ethanol concentrations and pharmacokinetics of ethanol in blood and expired gas during and after an i.v. infusion of ethanol during surgery. The experiment was repeated on the same subjects in the awake state.

Patients and methods

We studied 10 healthy women, aged 24–62 (mean 44) yr and with a body weight of 50–83 (mean 67) kg. They were consecutive patients admitted for elective ENT surgery with an estimated duration of more than 2 h. The study was approved by the local Ethics Committee and all patients gave informed consent to participate in two studies, one during general anaesthesia and one in the awake state about 2–6 weeks later.

In the first study, subjects were premedicated with triazolam 0.25 mg by mouth. General anaesthesia was induced with thiopentone and fentanyl, followed by atracurium or vecuronium. The lungs were ventilated using a circuit system (Q-system, Anmedic AB, Vallentuna, Sweden) with a bag-in-bottle, soda lime absorber and a heat and moisture exchanger (Humid-Vent 2 Port, Gibeck Respiration AB, Upplands Väsby, Sweden) with isoflurane and nitrous oxide in oxygen. After preoxygenation and denitrogenation for 5 min, a fresh gas flow of 6 litre min^{-1} was used during the first 5 min after tracheal intubation. During steady-state ventilation, the fresh gas flow was reduced to 1.5 litre min^{-1}. Body temperature was measured by an oesophageal probe (Datex/Instrumentarium Oy, Helsinki, Finland).

After general anaesthesia had been induced, we administered 0.4 g kg^{-1} of ethanol at a constant rate over 30 min by infusing a solution containing 10% ethanol and 5% glucose (w/v) with an infusion pump (Ivac 560, Ivac Co., San Diego, CA, USA) through a venous cannula placed in one arm.

Starting from the onset of infusion, concentrations of ethanol in blood and expired gas were measured at 20 exactly timed occasions over 2 h. Venous blood was sampled from a cannula placed in the arm opposite to that used for infusion and ethanol concentration was measured by gas chromatography (GC 6000 Vega Series 2, Carlo Erba Instruments, Milan, Italy). To avoid the "salting-out" effect of sodium fluoride used as an anticoagulant for whole blood [8], we analysed plasma samples and converted the ethanol concentration to whole blood data based

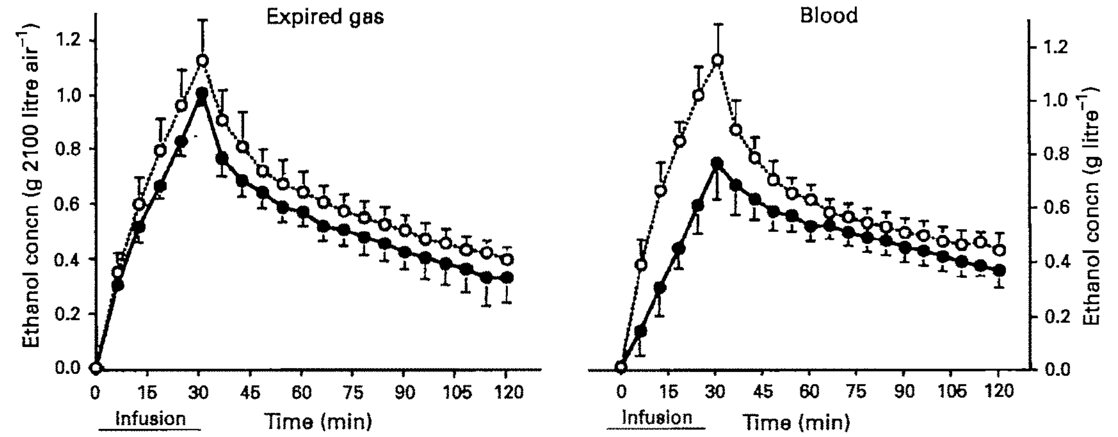

Figure 1 Expired gas and blood ethanol concentrations during i.v. infusion of 0.4 g kg^{-1} of ethanol in 10 women during isoflurane anaesthesia (○) and in the awake state (●) (mean, SD).

on a plasma–whole blood ratio of 1.10 [9]. Each sample was analysed twice and the mean value obtained. Duplicate analyses ensured a coefficient of variation of 1.7 %.

Ethanol concentration in expired gas was measured by a fuel cell type alcohol sensor (Alcolmeter S-D2, Lion Laboratories Ltd, S. Glamorgan, Wales). The breathalyser was calibrated by alcohol-in-gas standards before each study. To facilitate comparison with the blood ethanol concentration, the Alcolmeter readings were expressed in grams per 2100 litre of air. Accuracy was within 0.01 g per 2100 litre of air. Before each measurement, fresh gas flow was shut off by closing the circuit for 30 s. A 1.5-ml sample of air was taken at the end of passive expiration by attaching the Alcolmeter to an adapter placed between the tracheal tube and the heat and moisture exchanger of the ventilation system [6].

The second study was also performed at the hospital and followed the same design for ethanol infusion and plasma sampling as the first. The patient was conscious and no drug other than alcohol was given. She was instructed to take a deep breath and to blow into the mouthpiece of the Alcolmeter. Body temperature was measured by an earprobe (First Temp Genius 3000 A, Sherwood Medical, Carlsbad, CA, USA) which was calibrated to show the same values as the oesophageal probe.

In five patients where the operation ended earlier than expected, only data obtained during low-flow anaesthesia (mean 15.5) are reported. The corresponding measurements obtained during the second experiment were also discarded. This allowed comparisons between the anaesthetized and awake patients to be made at all times.

To avoid problems associated with computing the variance of a ratio, the blood–expired gas partition coefficient of ethanol was calculated as the difference between logarithm-transformed individual expired gas and blood ethanol values. The data were converted to the original scale and then multiplied by 2100.

The pharmacokinetics of ethanol were studied by assuming that the ethanol concentration equals the sum of a first-order distribution function and a zero-order saturated Michaelis–Menten elimination function. The concentration (C) at any time after a bolus injection of ethanol was obtained as [10];

$$C = A\mathrm{e}^{-\alpha t} + B - \beta t$$

where α = first-order exponential rate constant, β = zero-order elimination rate constant and t = time after the start of infusion. A and B = concentrations of ethanol obtained when the first-order and the zero-order functions are extrapolated back to $t = 0$.

We curve-fitted the data by considering the effect of an i.v. infusion on the model variables according to the following equations [11]:

During infusion:

$$C = (A/\alpha T)(1-\mathrm{e}^{-\alpha t}) + (Bt/T) - \beta t$$

After infusion:

$$C = A[(1-e^{-\alpha T})/\alpha T]\,\mathrm{e}^{-\alpha(t-T)} + (B - \beta t)$$

where T = infusion time.

The model variables were estimated by using a non-linear curve fitting program for a digital computer (Model-PK, McPherson Scientific, Rosanna, Victoria, Australia). No weighting factor was used as the error in the blood-ethanol analysis was constant within the concentration range studied. The ethanol values were consistently higher than the Michaelis constant for alcohol dehydrogenase, which is 0.05–0.10 g litre^{-1} [12].

The volume of the central compartment (V_c) was obtained from the dose of ethanol divided by the sum of A and B. The total distribution volume (V^{extrap}) was obtained from the dose divided by B [13].

Results are presented as mean (SD). The area under the concentration–time curve for ethanol (AUC) during the experiment was calculated by the linear trapezoidal method. The statistical calculations were performed on a Macintosh computer using StatView 4.01 (Abacus Concepts, Berkeley, CA, USA). Differences were evaluated by the paired t test and Wilcoxon's matched pair test, as appropriate, and reported to be significant when $P < 0.05$.

Results

The ethanol concentration in expired air was 13 % higher during general anaesthesia than in the awake

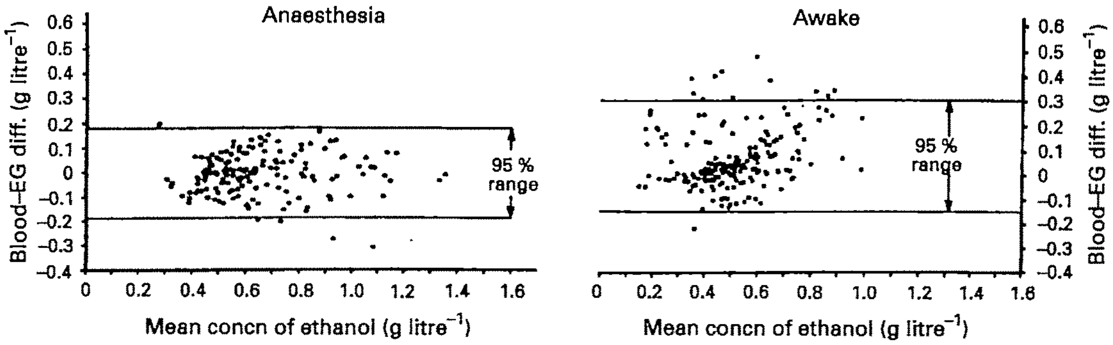

Figure 2 Agreement between ethanol concentrations in expired gas (EG) (× 2100) and blood in experiments with ethanol infusions during general anaesthesia (mean difference −0.005 (0.085)) ($n = 156$) and in the awake state (mean difference 0.062 (0.120)) ($n = 190$).

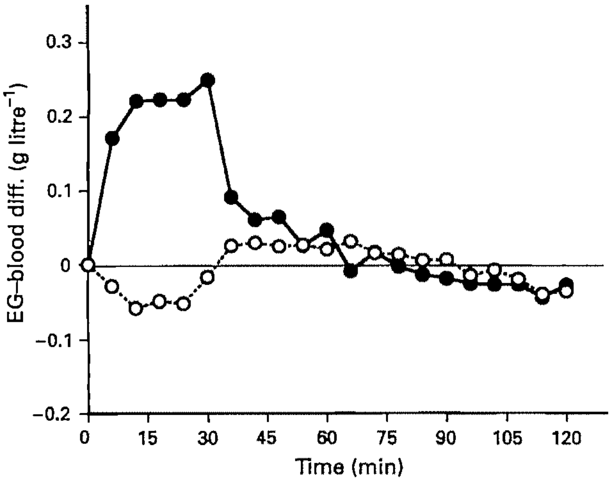

Figure 3 Expired gas (EG)–blood difference in ethanol concentration during and after i.v. infusion of ethanol during isoflurane anaesthesia (○) and in the awake state (●) (mean). Ethanol concentration in expired gas was expressed as the amount found in 2100 litre of air.

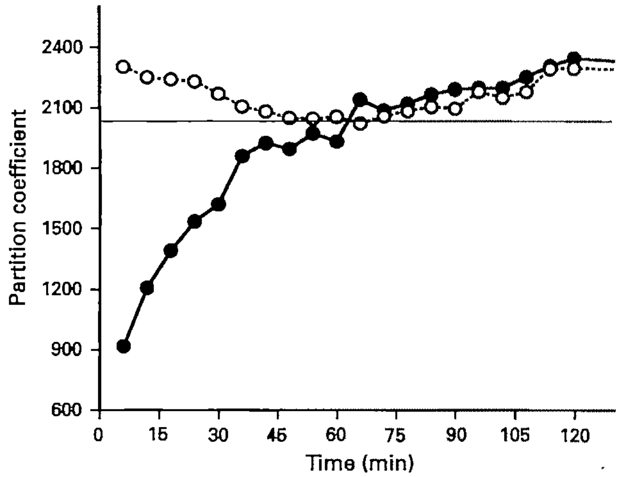

Figure 4 Blood–expired gas partition coefficient of ethanol during isoflurane anaesthesia (○) and in the awake state (●) (mean). Ethanol concentration in expired gas was expressed as the amount found in 2100 litre of air.

state (fig. 1). In venous blood, this difference was 34 % (fig. 1). The agreement between expired air and blood samples was stronger during general anaesthesia than in the awake state (fig. 2).

The expired gas–venous differences in ethanol concentration were close to zero during infusions of ethanol in anaesthetized patients, while they were markedly positive when the patients were awake (AUC, $P < 0.05$). After infusion, these differences were reduced and remained slightly negative during the pseudolinear phase of ethanol elimination (fig. 3).

These relationships represented a blood–expired gas partition coefficient for ethanol of 2238 (356) during infusion of ethanol in anaesthetized patients, while it was only 1339 (411) when the patients were awake. After infusion, these coefficients were 2107 (275) and 2118 (257), respectively (fig. 4).

The pharmacokinetic rate constants describing the distribution and elimination of ethanol showed similar values, regardless of whether or not the subjects were anaesthetized (table 1). However, V_c for ethanol in blood was only half as large during general anaesthesia (Wilcoxon's test, $P < 0.03$).

Body temperature was lower in anaesthetized compared with awake patients. The difference increased gradually from 0.5 °C and 1.5 °C but was significant at all times (table 2).

Discussion

We have found that breath sampling during isoflurane anaesthesia reflected the alcohol load well and with the same precision as in the conscious state. The slightly higher mean ethanol concentration obtained during anaesthesia must be considered in view of the markedly increased ethanol concentration in blood that returned to the lungs. This increase can be attributed to the reduction in central distribution volume (V_c) for ethanol. That a reduction in V_c could be detected in venous blood but not in expired gas indicates that it occurred after the blood had passed the pulmonary circulation, namely at the capillary level in peripheral tissues.

The distribution of ethanol to and from the tissues implies that the expired gas–venous difference in concentration is positive during ethanol infusion and becomes negative when mixing is complete throughout the total body water [14, 15]. This pattern was seen when our patients were awake, but the positive difference observed during infusion was absent when they were anaesthetized. The negligible expired gas–blood difference is consistent with vaso-

Table 1 Pharmacokinetic variables of ethanol (mean (SD)) derived by curve fitting concentration–time data obtained from analysis of ethanol concentration in expired gas ($\times 2100$) and venous blood. 120	35.5 (0.5)	37.0 (0.4)

dilatation, which decreases the transit time for blood in the tissues and results in less complete mixing of ethanol between the blood and interstitial fluid [16]. (The even slightly negative expired gas–venous difference can be explained by an expired gas–arterial difference averaging -0.06 g litre^{-1} during rapid infusion of ethanol [15].) Vasodilatation "arterializes" venous samples and also makes the concentrations in expired gas and venous blood more similar. Recent experiments in which local vasodilatation was induced by warming the site used for blood sampling confirmed that such treatment reduces V_c for ethanol [15].

The rationale for measuring ethanol in expired gas is based on the assumption of a fairly stable equilibrium between ethanol concentration in the capillary blood of the lungs and alveolar air. The agreement between the blood and expired gas data is usually reported after multiplying the expired gas concentration with the blood–expired gas partition coefficient. However, this coefficient tells us that the ethanol concentration is always about 2100 times higher in blood than in expired gas. Therefore, reabsorption of ethanol from the gas mixture in the breathing system is only a theoretical source of ethanol administration in anaesthetized patients.

Preliminary experiments showed that the heat and moisture exchanger and soda lime together absorbed about 30% of the ethanol in the breathing system. This suggests that sampling should be performed close to the tracheal tube for accurate analysis of end-expiratory ethanol concentration [6] and that the results are probably unaffected by ethanol in inspired gas. The confounding effect of using an extremely small fresh gas flow was challenged further by turning it off completely for 30 s before each breath sampling. However, our results imply no bias in the breath analysis from this practice. During both experiments, the blood–expired gas partition coefficient for ethanol during the pseudolinear phase of ethanol metabolism was 2113, on average, which was similar to that found in previous studies [6–8, 12]. On the other hand, this coefficient was markedly lower during infusion of ethanol in awake patients [14] which suggests that a close correlation between expired gas and venous blood samples during rapid absorption of irrigating fluid marked with ethanol cannot be expected. In fact, the agreement between expired gas and blood was closer during anaesthesia.

The present study suggests that anaesthesia-induced vasodilatation is the main confounder when measuring fluid absorption by ethanol monitoring during surgery. This view implies that the effects of atelectasis, tracheal intubation and moderate hypothermia on breath alcohol analyses are very small or cancel out. In particular, the lower body temperature in the anaesthetized patients would be expected to increase the blood–expired gas partition coefficient of ethanol by almost 10% during the pseudolinear phase of ethanol metabolism [7, 8]. However, this coefficient was almost identical in the groups at that time.

The pharmacokinetic model we used allows separate evaluation of the distribution and the elimination parts of the blood-ethanol concentration profile. A previous study showed that the half-time for distribution of ethanol into the total body water ($T_{\frac{1}{2}}^{\alpha}$) averaged 6.6 min after i.v. infusion of ethanol at different rates in young men and women [10]. In our present report, $T_{\frac{1}{2}}^{\alpha}$ was 6.9 min in venous blood when the female subjects were awake. In the anaesthetized state, we expected that the higher venous return of ethanol would correspond to a prolonged $T_{\frac{1}{2}}^{\alpha}$. Instead, it tended to be shorter. This result, and the fact that equilibration of ethanol requires as long as 30 min to become complete, supports the assumption that α represents equilibration between well perfused and poorly perfused anatomical regions of the body rather than across the cellular membranes [15].

Perioperative mucosal pH and splanchnic endotoxin concentration in orthotopic liver transplantation[†]

Summary

Although impairment of splanchnic perfusion may induce mucosal hypoxia and endotoxaemia during orthotopic liver transplantation (OLT), little is known about the changes in mucosal oxygenation during and after the procedure. To study the effects of liver surgery itself on mucosal pH (pH_i) and the response of pH_i to acute changes in portal flow, we measured gastric pH_i during six liver resections using tonometry: in two patients, after clamping of the hepatoduodenal ligament, pH_i decreased within 30 min and recovered promptly after reperfusion. We then investigated gastric and sigmoid pH_i (pH_{ig}, pH_{is}) during the perioperative phase in 18 OLT. Median pH_i values were low before surgery (pH_{ig} 7.28 (first/third quartiles 7.22/7.34); pH_{is} 7.27 (7.12/7.36)). Although global oxygen delivery and haemodynamic variables remained constant and veno-venous bypass (VVB) was used to maintain portal flow, pH_i declined during the anhepatic phase (pH_{ig} 7.19 (7.13/7.23), $P < 0.01$; pH_{is} 7.13 (7.06/7.24), $P < 0.05$). After reperfusion of the graft, pH_i recovered and did not differ from baseline values by the end of OLT. After operation pH_{ig} increased further, reaching the highest values 30 h after ICU admission (7.34 (7.26/7.38)). In the intraoperative period, no significant endotoxaemia was observed either in portal or systemic blood. The maximum reduction in pH_i was related neither to the duration of VVB and OLT nor to the number of red cell units transfused. pH_i after reperfusion did not correlate with graft viability or dysfunction of the lung or kidney. We conclude that pH_i indicates mucosal ischaemia during OLT which is not necessarily associated with endotoxaemia, and intraoperative pH_i monitoring does not appear to be a valuable predictor of postoperative graft failure and organ dysfunction. (*Br. J. Anaesth.* 1996; **76**: 90–98)

Key words

Liver, transplantation. Gastrointestinal tract, pH. Monitoring, pH oesophageal.

Perioperative changes in haemodynamic and metabolic variables and in tissue oxygenation are well established during orthotopic liver transplantation (OLT) [1, 2]. However, little is known about regional perfusion and oxygenation, particularly of the splanchnic organs, although intestinal hypoxia may be a source of postoperative morbidity and graft dysfunction [3–5]. In patients with liver failure secondary to cirrhosis and presenting with a hyperdynamic circulatory state, impaired tissue oxygenation has been observed during operation, although global oxygen delivery and perfusion pressure were adequately maintained [2]. It may be postulated that inadequate tissue oxygenation occurs during transplantation in the intestinal mucosa, which is highly susceptible to a reduction in blood flow. This might be most relevant during the anhepatic phase, when clamping of the portal vein is required for the recipient hepatectomy. Impaired intestinal perfusion may induce mucosal barrier dysfunction and translocation of bacteria and endotoxin into the systemic and lymph circulations [4, 6, 7].

Endotoxaemia has been reported to occur during OLT. The highest endotoxin concentrations were measured at the end of the anhepatic phase before reperfusion of the graft, and endotoxaemia was found to correlate with postoperative patient outcome [8, 9]. To avoid the deleterious effects of portal clamping on intestinal perfusion and to limit the progression of tissue hypoxia, veno-venous bypass (VVB), which drains blood from the portal to the superior caval vein, has been suggested [2, 10]. Mucosal oxygenation, however, has not been assessed adequately during liver transplantation. It is not known if mucosal ischaemia occurs during OLT, if it is associated with endotoxaemia or if the use of VVB preserves mucosal oxygenation.

To assess mucosal oxygenation, we measured gastrointestinal mucosal pH (pH_i) using tonometry [11]. In experimental studies pH_i was found to be a sensitive marker of impaired intestinal blood flow [12–14] and adequacy of mucosal oxygen delivery [15]. In clinical trials a low pH_i has been shown to be

an indicator of intestinal ischaemia after aortic surgery [16] and cardiopulmonary bypass [17], and a prognostic factor in critically ill patients [18, 19]. More recently, *gastric* pH_i measured 30 min after graft reperfusion has been reported to be an independent indicator of early graft viability in OLT [5].

The purpose of this study was to assess gastric and sigmoid mucosal pH during the perioperative phase of OLT. We hypothesized that preservation of splanchnic blood flow using VVB would prevent a reduction in pH_i during the anhepatic phase, a low pH_i would be related to the occurrence of endotoxaemia and low pH_i values persisting after graft reperfusion would be an indicator of poor graft function.

Because at the time this study was performed VVB was used routinely for haemodynamic support during OLT in our institution, we could not include a control group without VVB. To assess the ability of pH_i to detect acute intraoperative changes of mucosal perfusion in humans and to determine the effects of laparotomy and hepatic surgery on mucosal oxygenation, we measured gastric pH_i in six patients undergoing hepatic resection before the study in OLT patients. However, it was not our intention to compare the results obtained in liver resection patients with those obtained in the different patient populations undergoing OLT.

Patients and methods

After obtaining approval from the local Ethics Committee and informed consent, we studied six patients undergoing liver resection and 18 consecutive OLT in 16 adult patients. Patient characteristics and indications for hepatic resection or transplantation are summarized in tables 1 and 2.

One hour before surgery flunitrazepam 1–2 mg orally was given for premedication. Anaesthesia was induced with either thiopentone 3–5 mg kg^{-1} or etomidate 0.1–0.3 mg kg^{-1}, fentanyl 3–7 µg kg^{-1} and pancuronium 0.1 mg kg^{-1}, and maintained with 0.4–1.0 vol% isoflurane, a continuous infusion of fentanyl 3.5–7.0 µg kg^{-1} h^{-1} and incremental doses of pancuronium. The trachea was intubated and the lungs ventilated throughout OLT with 50% oxygen in air. Tidal volume and ventilatory frequency were adjusted to maintain Pa_{CO_2} at 4.8–5.3 kPa.

Standard monitoring included a 20-gauge radial artery catheter, a 12-French gauge triple-lumen central venous catheter and a 7-French gauge triple-lumen thermodilution fibreoptic pulmonary artery catheter (Abbott Critical Care, Mountain View, CA, USA). For perioperative antiobiotic prophylaxis, imipenem 0.5–1 g was given before operation. Selective digestive decontamination (SDD) was started 1 h before operation and repeated every 6 h by oral administration of polymyxin 50 mg, gentamicin 80 mg, vancomycin 125 mg and amphotericin B 5 ml [20]. Five patients had received systemic antibiotics for several days before operation. Gastric acid secretion was blocked before induction of anaesthesia with omeprazole 40 mg i.v. [21].

After induction of anaesthesia, tonometry catheters (Tonomomitor, Tonometrics, Worcester, MA, USA) were positioned in the stomach and the sigmoid colon. The correct position of the balloon was confirmed by intraoperative palpation. The colon had been emptied before operation by enema. The gastric catheter was left in place until the second postoperative day while the sigmoid catheter was removed at the end of surgery to avoid anal pressure necrosis.

The surgical procedure was standardized and all transplantations were performed by the same two surgeons (K.-W.J., E.P.) Orthotopic transplantation was performed in all patients. After percutaneous insertion of jugular (15- or 17-French gauge) and femoral (17-French gauge) cannulae and cannulation of the portal vein (24-French gauge wire-reinforced cannula) a heparin coated porto–femoro–jugular bypass (centrifugal pump, Biomedicus Medtronic, MN, USA) was used during the anhepatic phase. Bypass flow was adjusted initially to maximal values by increasing the pump speed near to the level where the portal or femoral vein collapsed. Flow rates ranged between 30 and 50% of actually measured cardiac output.

Red blood cells (RBC) were transfused to maintain packed cell volume (PCV) above 25%. Fresh frozen plasma (FFP) was substituted to increase partial thrombin time to 50% of normal reference values. Platelet concentrates were given when the platelet count was less than 30×10^9 $litre^{-1}$, depending on platelet function, determined from *ex vivo* bleeding time and volume [22].

Haemodynamic measurements were made, including: heart rate (HR), mean arterial pressure (MAP), mean pulmonary arterial pressure (PAP), central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP). Cardiac output (CO) was obtained from triplicate thermodilution measurements varying by less than 10%, performed randomly throughout the respiratory cycle. Core body temperature was recorded from the thermistor of the pulmonary artery catheter.

Central venous blood samples were obtained for serial analyses of haemoglobin, PCV, platelet count, coagulation profile (PT, aPTT, antithrombin III, fibrinogen), electrolyte (sodium, potassium, ionized calcium) and glucose concentrations. In addition, alanine–leucine transferase (ALT; optical standard method of DGKC, Boehringer Mannheim, Germany), coagulation factor V (optical method, CA 5000) and creatinine clearance (serum creatinine, Jaffe method, Boehringer Mannheim, Germany) were determined after operation. Arterial and pulmonary arterial blood samples were obtained for blood-gas analyses and measurement of oxygen saturation (ABL 520 Radiometer, Copenhagen, Denmark). Global oxygen delivery (Do_2) and consumption indices ($\dot{V}o_2$) in addition to oxygen extraction ratio were calculated from arterial and mixed venous oxygen contents and thermodilution derived CO. For measurement of plasma lactate concentration, blood samples from the pulmonary artery and portal vein were stored immediately on ice, centrifuged and analysed within 15 min (Kodak Ektachem Clinical Chemistry slide for lactate).

Plasma endotoxin concentration was measured using the limulus amoebocyte lysate test (Coatest Endotoxin, Chromogenix, Mölndal, Sweden). Blood samples from a separate lumen of the central venous catheter, the portal vein and the portal bypass catheter (during VVB) were obtained in pyrogen-free disposable syringes, anticoagulated with heparin, centrifuged immediately on ice for 5 min at 1200 rpm, and stored at −80 °C for later analysis. Standards were obtained from *E. coli* endotoxin (0111:B4 standard endotoxin) in sterile water. The sensitivity of the test in our laboratory is 1.0 pg ml^{-1}.

Gastric and sigmoid tonometer balloons were filled with 5 ml of room temperature normal saline. For measurement of pH_i, the first 1 ml of saline aspirated from the balloon was discarded (dead-space), and the remaining fluid was collected and immediately analysed for $P\text{CO}_2$ ($P\text{CO}_2$tono; ABL 520, Radiometer, Copenhagen, Denmark). Immediately after each collection, the tonometer was refilled. Simultaneously, an arterial blood-gas sample was obtained. Blood-gas analysis was performed at 37 °C without correction for temperature. pH_i was calculated from arterial HCO_3^- and $P\text{CO}_2$tono using a modified Henderson–Hasselbalch equation [11]. Because equilibration of carbon dioxide between saline in the balloon and mucosa is time and temperature dependent, $P\text{CO}_2$tono was corrected for dwell time and core temperature by multiplying the measured value by a correction factor (Tonometrics product insert 002-TGS) [16]. To avoid over extrapolation, the dwell time was extended as long as possible between consecutive intraoperative measurements (mean 48 (SD 21) min).

Intraoperative measurements were performed before bypass (I), 30 min after the start of VVB (II), 5 min before reperfusion of the graft (III), 30 min into the neohepatic phase (IV) and at the end of surgery when the peritoneum was closed (V). After operation, haemodynamic and oxygenation variables and gastric pH_i were assessed 6 h after admission to the intensive care unit (ICU; VI) and 12 (VII) and 24 h (VIII) later.

Before the study in OLT patients, we measured gastric pH_i in six patients undergoing liver resection (table 1). The perioperative regimen was the same as in the OLT patients except that SDD was not administered. The same haemodynamic, oxygenation and laboratory variables were assessed except for sigmoid pH_i and endotoxin concentration. In two patients the hepatic artery and portal vein were clamped for 41 and 63 min, respectively, to reduce bleeding from the hepatic resection surface.

Measurements were obtained after induction of anaesthesia, before surgery, 30 min after skin incision, during liver resection and at skin closure. In patients with clamping of the hepatoduodenal ligament, additional measurements were performed during clamping.

STATISTICAL ANALYSIS

The Kolmogorov–Smirnov test revealed non-normal distribution of data; therefore, non-parametric tests were used. Friedman's test was performed to examine the effect of time (SPSS for Windows, SPSS Software, Munich, Germany). For significant *F* values the following measurements were compared by Wilcoxon signed ranks test: before VVB (I) *vs* VVB (III), before bypass (I) *vs* end of surgery (V), and before bypass (I) *vs* 24 h after ICU admission (VIII). Bonferroni correction was applied as appropriate and differences were considered significant if $P < 0.05$. Bivariate correlations between pH_i and blood-gas variables and between pH_i and duration of VVB, duration of surgery and blood loss were determined by Spearman's rank correlation test. Data are reported as median (first/third quartiles).

Results

Patient data, indications for surgery and transfusion requirements of patients undergoing hepatic resection are presented in table 1.

Haemodynamic and oxygenation variables remained unchanged throughout surgery (data not shown). Although pH_i decreased slightly in all patients after laparotomy, no significant overall effects of time were observed for arterial pH and gastric pH_i (Friedman test: $P = 0.22$ for arterial pH, $P = 0.1$ for pH_i) (fig. 1). In the two patients, in whom portal blood flow was interrupted transiently by clamping of the hepatoduodenal ligament, pH_i decreased instantaneously. The lowest pH_i value (6.95) was encountered in the patient with the longest clamping time (63 min). After release of the portal clamp, pH_i returned to the range of baseline values and did not differ from pH_i in patients without portal clamping by the end of surgery.

Patient data, indications for transplantation, duration of surgery and VVB, respectively, units of RBC and FFP transfused, and duration of postoperative ventilatory support and ICU stay in OLT patients are summarized in table 2. Cirrhosis was the most common indication for transplantation (13 of 16 patients). In two patients, re-transplantation was performed 4 and 51 days after the first transplantation for primary graft non-function and

chronic rejection, respectively. RBC and FFP requirements were highest during the anhepatic phase.

Central haemodynamic variables and Do_2 index were essentially unchanged throughout the peri-operative period (table 3). MAP declined slightly during the anhepatic and neohepatic phases and was significantly lower at the end compared with the beginning of surgery ($P < 0.01$). CI remained high, which is typical for patients presenting with cirrhosis. $\dot{V}o_2$ index changed significantly over time (Friedman test: $P = 0.02$); $\dot{V}o_2$ index was low during OLT and increased after admission to the ICU (table 3).

The perioperative course of mixed venous lactate concentration, mixed venous oxygen saturation ($S\bar{v}_{O_2}$), arterial pH, gastric and sigmoid pH$_i$, and endotoxin concentrations in mixed venous and portal blood is shown in figure 2. Mixed venous lactate concentration increased continuously during transplantation, peaked after graft reperfusion (5.9 (3.5/7.15) mmol litre^{-1}; $P < 0.01$ *vs* baseline) and declined to baseline values 30 h after ICU admission. $S\bar{v}_{O_2}$ remained constant at a high level (> 87%) during OLT, began to decline after operation and reached its lowest value 30 h after ICU admission (76 (70/79)%; $P < 0.01$ *vs* baseline). Arterial pH decreased significantly from 7.39 (7.35/7.43) at the beginning of OLT to 7.32 (7.24/7.34) during VVB ($P < 0.01$). To prevent further progression of metabolic acidosis, sodium bicarbonate (110 mmol) was given to 12 patients during the anhepatic or neohepatic phase. After reperfusion of the graft, arterial pH remained less than baseline values and recovered to normal values after ICU admission.

Gastric pH$_i$ (pH$_{ig}$) decreased significantly from baseline values of 7.28 (7.22/7.34) to 7.19 (7.13/7.23) during VVB ($P < 0.01$) and remained low during the anhepatic phase. After reperfusion of the graft, pH$_i$ increased within 30 min and did not differ from baseline values at the end of OLT (ns). After operation, gastric pH$_i$ increased further, reaching the highest values 18 and 30 h after ICU admission (7.34 (7.28/7.38) and 7.34 (7.26/7.38), respectively). After adjusting for multiple comparisons, the difference in gastric pH$_i$ between baseline and 30 h ICU did,

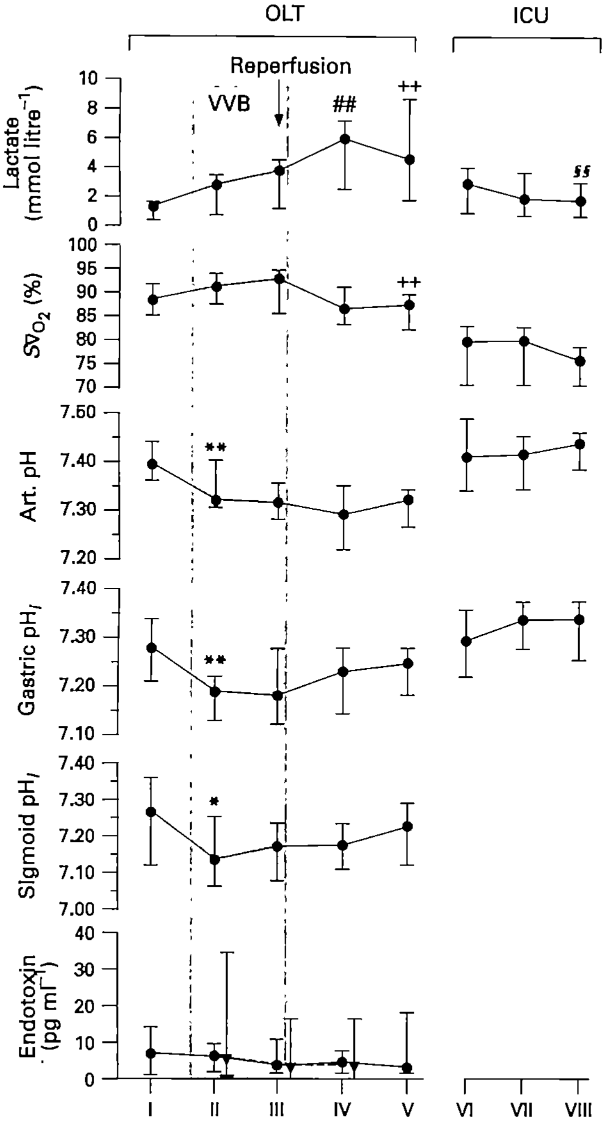

Figure 2 Arterial lactate concentration, mixed venous oxygen saturation ($S\bar{v}_{O_2}$), arterial pH, gastric pH_i, sigmoid pH_i and mixed venous (●) and portal (▲) endotoxin concentration. The duration of veno-venous bypass (VVB) is represented by the shaded area. I = before VVB; II = 30 min of VVB; III = 5 min before graft reperfusion; IV = 30 min after graft reperfusion; V = end of OLT; VI, VII, VIII = 6, 18 and 30 h after ICU admission, respectively. $^*P < 0.05$, $^{**}P < 0.01$: before VVB *vs* 30 min of VVB; $^{\#\#}P < 0.01$: 30 min of VVB *vs* 30 min of graft reperfusion; $^{\dagger\dagger}P < 0.01$: before VVB *vs* end of OLT; $^{\S\S}P < 0.01$: before VVB *vs* 30 h in ICU.

however, not reach statistical significance ($P = 0.1$). The intraoperative course of sigmoid pH_i (pH_{is}) showed essentially the same pattern as gastric pH_i; the lowest values were measured during VVB (7.13, 7.06/7.24), and sigmoid pH_i at the end of surgery did not differ significantly from baseline.

The maximal intraoperative decrease in gastric or sigmoid pH_i did not correlate either with the duration of VVB (pH_{ig}, $r = 0.17$; pH_{is}, $r = 0.34$; ns) or with the number of RBC units transfused (pH_{ig}, $r = -0.19$; pH_{is}, $r = 0.04$; ns). pH_i values obtained after graft reperfusion did not correlate with duration of postoperative ventilatory support (pH_{ig}, $r = 0.41$; pH_{is}, $r = 0.29$; ns) (table 2), duration of ICU stay (pH_{ig}, $r = 0.39$; pH_{is}, $r = 0.29$; ns) (table 2) or with creatinine clearance on the second postoperative day (pH_{ig}, $r = 0.34$; pH_{ig}, $r = -0.18$; ns) (table 4).

Table 4 Postoperative tests of hepatocellular integrity, hepatic function and renal function (median (Q1/Q3)). ALT = Alanine–leucine transferase; factor V = activity of coagulation factor V as a percentage of reference values of normal population; prothrombin time as a percentage of reference values of normal population; creatinine clearance as a percentage of reference values of normal population normalized for body surface area

	ICU	
	VI	VIII
ALT (U/L)	216 (96/397)	251 (109/676)
Factor V (%)	42 (18/68)	52 (9/77)
Prothrombin time (%)	52 (44/62)	48 (41/58)
Creatinine clearance (%)	—	71 (39/98)

Postoperative hepatic function, as assessed by plasma activity of factor V and prothrombin time (table 4), and the degree of hepatocellular damage, as assessed by serum ALT (table 4), did not correlate with pH_i after reperfusion of the graft (pH_{ig}, $r = 0.28$; pH_{is}, $r = 0.34$; ns) or at the end of surgery (pH_{ig}, $r = 0.31$; pH_{is}, $r = -0.15$; ns). In the one patient requiring re-transplantation for primary graft non-function, pH_i values after graft reperfusion (pH_{ig} 7.28, pH_{is} 7.23) and at the end of OLT (pH_{ig} 7.27, pH_{is} 7.28) were in the range obtained from patients with adequate primary graft function.

Plasma endotoxin concentrations were determined during the course of 12 OLT. Endotoxin concentrations in plasma from mixed venous or portal venous blood did not increase significantly during OLT (fig. 2). Correlation analysis revealed no statistically significant relationship between either portal or mixed venous endotoxin concentrations and the lowest values of gastric or sigmoid pH_i measured during the surgical procedure ($r = 0.45$, $r = 0.41$, respectively). One patient presented with high endotoxin concentrations during the anhepatic phase in both mixed venous (58 pg ml^{-1}) and portal blood (71 pg ml^{-1}); at the corresponding time, pH_i values were 7.09 and 7.14 in the stomach and sigmoid colon, respectively.

Discussion

A decrease in mucosal pH_i is considered to reflect inadequate oxygen delivery to the gut to meet metabolic demands. Accordingly, a close relationship between acute changes in splanchnic perfusion and mucosal pH_i has been demonstrated [13]. In pigs, pH_i measured using tonometry decreased as early as 20 min after partial occlusion of the superior mesenteric artery and returned to baseline values within 60 min after release of the occlusion [13]. Although tonometrically measured pH_i slightly underestimated the pH_i changes measured directly with a pH microelectrode, there was a close correlation between values obtained with both methods and the direction of pH_i changes was always reflected accurately by tonometry [13]. Thus the accuracy and response time of tonometry appears adequate to assess acute intraoperative alterations of intestinal perfusion in humans.

Indeed, our study in a limited number of patients undergoing liver resections confirmed that acute interruption of intestinal blood flow was reflected closely by a decrease in tonometrically measured gastric pH_i. In two of six patients in whom portal blood flow was interrupted intentionally by clamping of the hepatoduodenal ligament, gastric pH_i decreased within 30 min after portal occlusion and, after release of the portal clamp, returned to baseline values towards the end of surgery. In patients without portal clamping, pH_i remained essentially unchanged (fig. 1). An increase in gastric pH_i has also been reported after release of chronic intestinal ischaemia caused by portal thrombosis [23]. In contrast, a recent study on the effects of dopexamine on splanchnic oxygenation in cardiac surgical patients revealed that gastric pH_i did not adequately reflect changes in splanchnic blood flow, as measured by the indocyanine green dilution technique [24]. These apparently conflicting results may be caused by different underlying pathophysiological mechanisms; sudden mechanical interruption of venous outflow induces complete stasis of intestinal microvascular blood flow whereas a pharmacologically induced increase in arterial perfusion may redistribute microvascular flow.

Based on the results obtained during hepatic resection, the reversible reduction in both gastric and sigmoid pH_i during the anhepatic phase of OLT implies that transient intramural hypoxia of the gastrointestinal mucosa had developed. Moreover, pH_i decreased although portal blood flow was maintained by VVB allowing total flow rates of up to 50% of cardiac output. As intraoperative pH_i changes were essentially similar at both locations (stomach and sigmoid colon), the reduction in gastric pH_i also cannot be attributed to alterations in gastric mucosal perfusion as induced by surgical manipulations or falsely low pH_i values caused by reflux of alkaline duodenal fluid [25]. Although there are no data on microvascular mucosal perfusion during liver transplantation, the reduction in pH_i observed during the anhepatic phase suggests that preservation of overall portal blood flow by means of VVB did not achieve adequate distribution of intestinal blood flow. Inappropriate flow distribution has been suggested recently to explain the decrease in gastric pH_i, despite the increase in splanchnic oxygen delivery achieved in postoperative cardiac surgical patients by means of dopexamine [24]. In our study pH_i decreased as early as 30 min after the beginning of the anhepatic phase and this suggests that the short period of complete portal clamping necessary to allow insertion of the VVB cannula into the portal vein may be sufficiently long to induce prolonged impairment of microvascular mucosal perfusion. This is supported by the finding that the degree of mucosal acidosis was not related to the duration of VVB.

The increase in lactate concentration observed in our patients during OLT may be interpreted as an indicator of tissue hypoxia only with caution (fig. 2). Steib and colleagues found in a comparable group of hyperdynamic OLT patients that arterial lactate and $S\bar{v}_{O_2}$, indices of tissue oxygenation conventionally used in critically ill patients, failed to accurately reflect tissue hypoxia, as evidenced by supply dependent oxygen consumption [2]. During OLT, lactic acidosis appears to reflect more the absence of metabolic liver function than tissue hypoxia. Moreover, considerable amounts of lactate are added to circulating blood with each unit of stored blood transfused. In fact, we measured lactate concentrations higher than 30 mmol litre^{-1} in stored red cell concentrates (data not shown).

$D\text{O}_2$ index remained unchanged throughout OLT. Consistent with the results of Steib and colleagues, we observed a tendency towards a decreased $\dot{V}\text{O}_2$ index during the anhepatic phase, a finding attributable to a combination of intraoperative hypothermia (temperature at the end of OLT 33.7 (32.8/36.1) °C) and absence of metabolic liver function [2]. During operation, $S\bar{v}_{O_2}$ remained high, which is typical in cirrhotic patients (> 87%), and tended to increase further during the anhepatic phase (93 (86/95)% before reperfusion). As a consequence, continuous intraoperative $S\bar{v}_{O_2}$ monitoring appears to be an inappropriate method to detect tissue hypoxia in hyperdynamic cirrhotic patients. Although increased lactate and decreased $S\bar{v}_{O_2}$ appear not to be reliable markers of tissue hypoxia in cirrhotic patients undergoing OLT, tissue hypoxia has been suggested to be present during OLT, as evidenced by oxygen supply dependency [2]. The decrease in pH_i in the present study clearly demonstrated that the intestinal mucosa is one site of tissue hypoxia.

We are not aware of "normal values" for gastric or sigmoid pH_i in patients with liver cirrhosis. Baseline values in our patients were, however, low compared with normal values reported in the literature for cardiac surgical patients [23] and those regarded as the lower limit for therapeutic interventions in critically ill patients [18]. Thus chronic mucosal hypoxia may be present in end-stage liver cirrhosis associated with portal hypertension and massive collateral circulation. "Normalization" of gastric pH_i on the second postoperative day may indicate furthermore that elimination of portal hypertension and restoration of normal splanchnic perfusion after liver transplantation allow rapid improvement of mucosal blood flow and oxygenation.

We did not find a correlation between intraoperative gastric or sigmoid pH_i measured after reperfusion of the graft and postoperative graft viability. This is in contrast with the results of a recent study that reported a predictive value for postoperative early graft dysfunction of a gastric pH_i value < 7.32 measured 30 min after graft reperfusion [5]. Although this study included a larger number of patients ($n = 35$), its conclusion was based on only one patient requiring re-transplantation for primary graft non-function. More importantly, gastric pH_i values were consistently higher than arterial pH values, a finding attributable to incomplete equilibration of carbon dioxide between the mucosa and the tonometer [11]. In contrast, pH$_i$ in our study was always lower than arterial pH at the corresponding times. In the one patient requiring early re-transplantation, pH$_i$ values did not differ from those of the other patients with an uneventful postoperative course. Furthermore, we could not demonstrate a relationship between intraoperative pH$_i$ and postoperative function of other organ systems, as postoperative creatinine clearance, duration of ventilatory support and total duration of ICU stay were unrelated to intraoperative pH$_i$. It is noteworthy, however, that Downing and colleagues found an association between intraoperative pH$_i$ values < 7.32 and graft dysfunction, acute renal failure, sepsis and the need for ventilatory support after OLT [26]. Unfortunately, this report does not contain details on patient selection and use of tonometry. Moreover, despite the predictive value of pH$_i$ for postoperative complications, the mortality rate was not different between patients with pH$_i$ values higher than 7.32 or lower than 7.32.

In previous studies, endotoxaemia has been demonstrated during liver transplantation, although venous stasis during the anhepatic phase, which could have accelerated the translocation of endotoxin from the gut into the portal blood [6], was avoided by the use of VVB [8, 9]. Moreover, a high systemic endotoxin concentration was a prognostic factor for primary graft non-function, postoperative pulmonary complications and mortality [8, 9]. In our patients significant endotoxaemia was absent in portal and mixed venous blood, although the reduction in pH$_i$ suggested the presence of intraoperative mucosal hypoxia, a situation promoting translocation of enteric micro-organisms (fig. 2). The one patient in whom intraoperative endotoxaemia in both portal and systemic blood was proved had a normal graft function and an uneventful postoperative course. Even though we did not observe endotoxaemia, we cannot exclude the occurrence of translocation completely. First, pre- or perioperative administration of antibiotics and the use of SDD may have reduced the viability and number of enteric micro-organisms; in addition, binding of polymyxin to the lipid A portion of endotoxin may have prevented absorption of endotoxin from the gut [27, 28]. Second, portal and systemic blood may have been inappropriate sources to detect endotoxin. In liver transplantation in rats, bacteria were translocated to mesenteric lymph nodes within 20 min of portal vein occlusion [29]. Similarly, translocation of bacteria to mesenteric lymph nodes has been found in humans after abdominal trauma, however, without being associated with postoperative complications [30].

When interpreting mucosal acidosis the effects of systemic disturbances in acid–base balance on pH$_i$ have to be considered. It has been suggested that in the presence of systemic acidosis the difference between arterial and mucosal pH, the "pH$_i$ gap", would more accurately reflect changes in mucosal pH originating from regionally inadequate mucosal oxygenation [31]. In our study, we did not calculate the pH$_i$ gap, because this index has never been validated as an independent measure for the adequacy of mucosal oxygenation. Although it is conceivable that pH$_i$ decreases when systemic acidosis emerges, the fact that pH$_i$ in our patients increased rapidly after reperfusion of the graft while arterial pH remained low supports the concept that pH$_i$ primarily reflects local hydrogen ion production caused by anaerobic metabolism (fig. 2). Moreover, theoretical considerations suggest that mucosal acidosis is caused by local generation of hydrogen ions from anaerobic metabolism rather than stagnation of carbon dioxide removal as mucosal blood flow decreases [25].

To avoid the confounding effects of different blood-gas analysers while interpreting pH$_i$ values, we used the same blood-gas analyser, ABL 520 (Radiometer), in the OR and ICU [32]. This device has been shown to measure $P\text{CO}_2$ accurately in saline [31].

The hypothesis that VVB would mitigate the reduction in pH$_i$ was not strictly tested in this study. To estimate accurately the effects of preserved portal blood flow on mucosal oxygenation, it would have been necessary to compare OLT performed with and without VVB in a randomized study. However, because at the time this study was performed VVB was used routinely at our institution, we could not implement a randomized study design. Although we cannot exclude the possibility that pH$_i$ may have decreased to even lower values without the use of VVB, the finding of impaired mucosal oxygenation while portal blood flow was maintained suggests that additional mechanisms must account for the preservation of mucosal perfusion during OLT.

LABORATORY INVESTIGATIONS

Nitrous oxide or halothane, or both, fail to suppress c-*fos* expression in rat spinal cord dorsal horn neurones after subcutaneous formalin

W. Z. SUN, B. C. SHYU AND J. Y. SHIEH

Summary

In rats injected s.c. with formalin, behavioural correlates of the amount and pattern of Fos-like immunoreactivity (Fos-LI) (molecular responses to pain) were studied to test if early phase treatment with 75% nitrous oxide or 2% halothane, or both, suppressed subsequent spinal sensitization. Rats were allocated to four treatment groups: (1) 100% oxygen (control, $n = 15$), (2) 75% nitrous oxide (0.5 MAC, $n = 12$), (3) 2% halothane (1 MAC, $n = 12$), and (4) 75% nitrous oxide with 2% halothane (1.5 MAC, $n = 18$) for 20 min. Each rat then received a s.c. injection of 1% formalin 50 µl into the left hindpaw and anaesthesia was maintained for another 5 min (early phase). A fifth group of rats receiving fentanyl 100 µg kg^{-1} ($n = 12$) 10 min before formalin injection were studied simultaneously as a positive control. Rats in all groups were killed 60 min after formalin injection and maximal counts of Fos-LI labelled neurones in the dorsal horn of the rat spinal cord were compared according to laminar distribution. Formalin-induced behavioural hyperalgesia during the early phase was suppressed completely by fentanyl, 75% nitrous oxide, or 2% halothane, or both. The late phase response was attenuated by all four anaesthetic regimens within 20 min after injection, whereas behavioural scores for the nitrous oxide, halothane, or both, groups were nearly identical to the control 20 min later. Fentanyl suppressed the late phase response until 30 min after formalin injection but failed to reduce it thereafter. The numbers of Fos-LI labelled neurones for groups given nitrous oxide, or halothane, or both, were identical to the control, whereas numbers for fentanyl were 47.2% less ($P < 0.01$). The decrease occurred predominantly in the neck of the dorsal horn (44.9% of control, $P < 0.01$) and also in the nucleus proprius and superficial laminae (54.4% and 56.2% of control, $P < 0.05$). In summary, we found that nitrous oxide, or halothane, or both, did not suppress subsequent spinal sensitization to noxious stimulation. This result supports the previous hypothesis that inhalation anaesthesia lacks pre-emptive analgesic action. Inhalation anaesthetic agents, unlike fentanyl, suppress the early and late phase response because of anaesthetic but not analgesic effects. Thus, we suggest that measuring the genetic product of c-*fos* proto-oncogene is a useful adjunct to pharmacological tests whenever behavioural hyperalgesia is questionable or unobtainable. (*Br. J. Anaesth.* 1996; **76**: 99–105)

Key words

Analgesia, pre-emptive. Anaesthetics gases, nitrous oxide. Anaesthetics volatile, halothane. Anaesthetics i.v., fentanyl. Rat. Genetic factors, proto-oncogenes.

Inhalation anaesthetics are considered poor analgesics despite potent anaesthetic actions in producing surgical immobility. Wall hypothesized that lightly anaesthetizing the spinal cord fails to block the afferent signals set off during surgery, and that other treatments such as regional anaesthesia before skin incision are required to produce significant pre-emptive analgesia during inhalation anaesthesia [1]. The concept that prevention of intense nociceptor activation can suppress the subsequent hyperalgesic state has had a major impact on the practice of postoperative analgesia [2]. Although pre-emptive analgesia is well documented in animal models, the clinical evidence is less convincing [3]. A critical difference between humans and animal models is the method of pain assessment. In animal models, the sensitivity and specificity of behavioural responses as an index of nociception largely remain to be determined.

In contrast with previous hypotheses, recent studies based on formalin-induced behavioural hyperalgesia have demonstrated mild to moderate pre-emptive analgesia after volatile agents (i.e. halothane and isoflurane) [4, 5]. Paradoxically, this response was not found in rats receiving nitrous oxide with halothane, although their combined anaesthetic potency is greater than that of each agent alone. In a parallel study, nitrous oxide, but not halothane, induced dose-dependent pre-emptive analgesia that was partially reversed by naloxone and halothane [6]. The results of these studies vary

markedly despite identical variables being used. As discrepancies may occur as a result of general attenuation of behaviour because of the non-algesic effect of anaesthetics but not their analgesic effect [7], a further index is required to examine the analgesic effect of inhalation anaesthetics.

Unlike most physiological indices of pain, *c-fos* expression in the brain is least affected by various i.v. and inhalation anaesthetics [8–10]. The genetic products of *c-fos* expression are highly associated with neuronal sensitization in the central nervous system and with behavioural hyperalgesia [11]. The number of Fos-like immunoreactivity (Fos-LI) labelled neurones has been used widely to quantify the antinociceptive action of various analgesic agents [12, 13]. Various patterns of suppression for subpopulations of spinal nociceptive neurones may provide further understanding on how the antinociceptive process is involved [14]. By providing both qualitative and quantitative indices for pain, Fos-LI has been accepted as a morphological marker to assess the effectiveness of analgesia [15, 16]. In the present study we used Fos-LI as a biochemical correlate of behavioural indices to test if pre-stimulus inhalation anaesthesia with nitrous oxide or halothane, or both, differentially suppressed the subsequent spinal sensitization in the rat formalin model. To study the possible mechanism of the behavioural response, fentanyl was used as a positive control for analgesia.

Materials and methods

The studies were approved by the Institutional Animal Care Subcommittee of the National Taiwan University Hospital. Male Sprague–Dawley rats, weighing 300–350 g, were maintained in a 12-h light–dark cycle and allowed free access to food and water. Experiments were performed between 10:00 and 16:00 in a randomized order. Rats were allocated randomly to one of five groups: (1) control (100 % oxygen, $n = 15$), (2) 75 % nitrous oxide (0.5 MAC, $n = 12$), (3) 2 % halothane (1 MAC, $n = 12$), (4) 75 % nitrous oxide with 2 % halothane (1.5 MAC, $n = 18$), and (5) fentanyl 100 µg kg^{-1} in 100 % oxygen ($n = 12$). Two phases of response were defined: early (0–5 min) and late (5–60 min) [17]. The inspired concentrations of nitrous oxide and halothane (75 % and 2 %) were chosen to provide approximately 0.5 and 1 MAC of anaesthesia, respectively. These doses were calculated on the basis of MAC, 148–150 % for nitrous oxide and 0.95–1.11 % for halothane [18], and an estimated ratio of end-tidal-to-inspired concentration of halothane of 0.5–0.6 in spontaneously breathing rats after 20 min [19]. Anaesthesia was induced by placing the animals in a Plexiglas box prefilled and flushed continuously at 4 litre min^{-1} with one of the anaesthetics. Except for rats in the fentanyl group, which were given fentanyl 100 µg kg^{-1} i.p. 10 min before formalin, animals were left undisturbed for 20 min and then removed briefly from the box for injection of formalin. To ensure an adequate anaesthetic level on injection, rats receiving halothane and nitrous oxide–halothane were subject to further anaesthesia until the corneal reflex and withdrawal to forceful pinch of the forepaw were absent. Animals were returned to the box immediately after injection and maintained under anaesthesia for another 5 min (early phase). Rats were then transferred to a clear open cage and allowed to recover, and their behaviour was observed by a blinded observer for 60 min after formalin injection (late phase). During the recovery phase from inhalation anaesthesia, the forepaw was pinched every 30 s to monitor the level of anaesthesia until spontaneous movement occurred. All gas concentrations were monitored continuously and maintained at the desired level with an attached gas analyser (RGM 5250 Ohmeda, Madison).

FORMALIN TEST

Diluted (1 %) formalin was prepared freshly from 37 % formaldehyde with 0.9 % normal saline before use; 50 µl was injected s.c. into the plantar surface of the left hindpaw using a 26-gauge needle. With a computer program designed by one of the authors (B.C.S.), the amount of time spent in each of four behavioural categories, 0–3, was recorded and calculated every minute, as described by Dubuisson and Dennis [20]. In brief, the categories were: 0 = the injected paw is not favoured (i.e. foot flat on floor with toes splayed); 1 = the injected paw has little or no weight on it with no toe splaying; 2 = the injected paw is elevated and the heel is not in contact with any surface; 3 = the injected paw is licked, bitten or shaken. The scores were then averaged at 5-min intervals. To investigate further the temporal pattern of behavioural responses, the scores were summed for six time intervals: 5–60, 10–60, 20–60, 30–60, 40–50 and 50–60 min, respectively. The summed score was used to facilitate comparison of behaviour with the amount of Fos-LI produced over 0–60 min after injection.

IMMUNOHISTOCHEMISTRY

All animals were killed 60 min after formalin injection. Animals were anaesthetized deeply with an overdose of sodium pentobarbitone and perfused transcardially with saline followed by 4 % paraformaldehyde in phosphate buffer 0.1 mol litre^{-1} (pH = 7.4). The spinal cord at the lumbar enlargement was removed, post-fixed for 4 h, and cryoprotected overnight in 30 % sucrose. Frozen sections were cut in a cryostat (30 µm) and collected as free-floating sections. Sections were incubated with primary rabbit polyclonal anti-Fos antiserum (Ab-2, Oncogene), diluted 1:750 with PBS 0.1 mol litre^{-1}, containing 3 % normal goat serum (NGS) and 0.3 % Triton X-100 for 48 h at 4 °C. After being washed in PBS, they were incubated with biotinylated second antibody (goat anti-rabbit antiserum; Vector) diluted 1:200 in PBS for 1 h at room temperature. Sections were reacted with elite ABC (Vectastain) diluted 1:50 for 1 h and then 0.1 % diaminobenzidine solution containing 0.6 % nickel ammonium sulphate and 0.2 % H_2O_2 as substrate was added. All sections were mounted on gelatin-subbed slides, air-dried and protected with a coverslip for light microscopic inspection. Two additional groups of rats, one of which received 75% nitrous oxide with 2% halothane but not formalin injection ($n = 2$), and other which received neither gas nor formalin ($n = 2$), were studied as negative controls for non-specific staining caused by either inhalation anaesthetics or animal manipulation. To examine the specificity of the primary antibody, non-specific staining was tested simultaneously for the control rats. Omission of the anti-c-*fos* antibody was prepared by immunoprecipitation with c-*fos* peptide (Oncogene) before the primary antibody reaction. Dark staining of the nucleus, as shown in the section treated with antibody alone, was completely absent. This approach ensured high quality of specificity for the antibody in use.

COUNTING OF FOS-LI LABELLED NEURONES

Fos-LI labelled neurones were examined throughout the L3–5 spinal segments and across the laminae. Sections were examined using a dark-field microscope (Axioscope, Zeiss) to determine the segmental level according to the grey matter landmarks, as described by Molander, Xu and Grant [21]. Under dark-field illumination, the dorsal horn of each section was divided further into three regions: (1) the superficial laminae (laminae I/II), (2) the nucleus proprius (laminae III/IV) and (3) the neck (laminae V/VI) [14]. Fos-LI labelled neurones were then examined with bright-field illumination at 100× magnification for each section. All images, in both dark- and bright-field illumination, were printed serially on glossy thermal paper via a connected CCD camera (Videl Lens, Cohu) and video copy processor (P67U, Mitsubishi). Fos-LI labelled neurones, which showed deep staining distinguishable from background, were counted from the printed images with respect to each lamina. To minimize further the individual bias for inspection, all images were duplicated and counted separately by two experienced laboratory assistants throughout the study. When the difference between duplicated counting was greater than 10% of each lamina, a third copy was made and inspected by one of the authors (W.Z.S.) Counts that were questionable in either quantity or quality were excluded. At least 10–15 sections were scanned for each segment, and three sections with the greatest number were selected. The observers who scored formalin-induced behavioural hyperalgesia and investigators who counted Fos-LI labelled neurones were all blind to the treatment of each animal.

DATA ANALYSIS

Statistical analysis was performed to compare the different groups of animals, using one-way analysis of variance (ANOVA) for the pain score at each time point and for the total number of Fos-LI labelled neurones, and two-way repeated measure ANOVA (treatment × lamina) for the number of labelled neurones and the laminar region. The Student–Newman–Keuls test was used for multiple comparisons. $P < 0.05$ was considered statistically significant.

Results

BEHAVIOURAL RESPONSES

S.c. injection of 1% formalin produced a similar biphasic pain response in the control group to that described by Dubuissen and Dennis [20]. A brief phase of intense pain (i.e. licking, biting and flinching of the injected paw) occurred in the first 5 min. Pain then subsided for 10 min, and a later phase

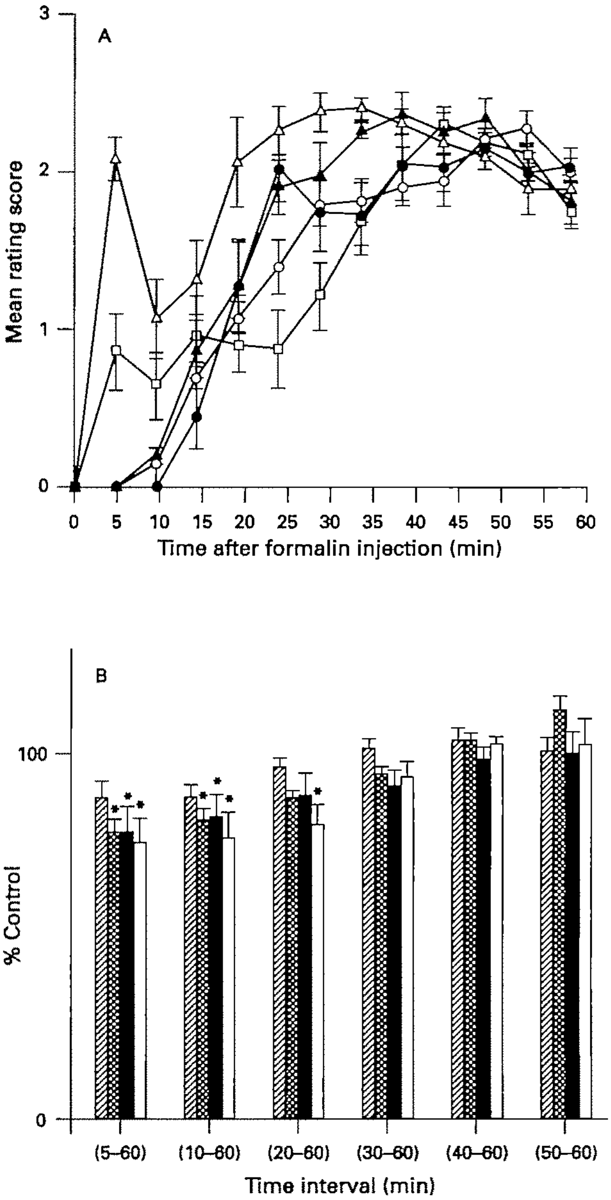

Figure 1. Time course of anaesthetic effects on formalin-induced pain score (mean, SEM). A: Pain score × minute plotted as a function of time after injection of formalin in the control (△), 75% nitrous oxide (▲), 2% halothane (○), 75% nitrous oxide with 2% halothane (●) and fentanyl 100 µg kg^{-1} (□) groups. B: Ratio of summed score in the experimental groups to control group (% of control) plotted as a function of time. ▨ = Nitrous oxide 75%, ▩ = 2% halothane, ■ = 75% nitrous oxide with 2% halothane and □ = fentanyl 100 µg kg^{-1}. * $P < 0.05$ compared with control.

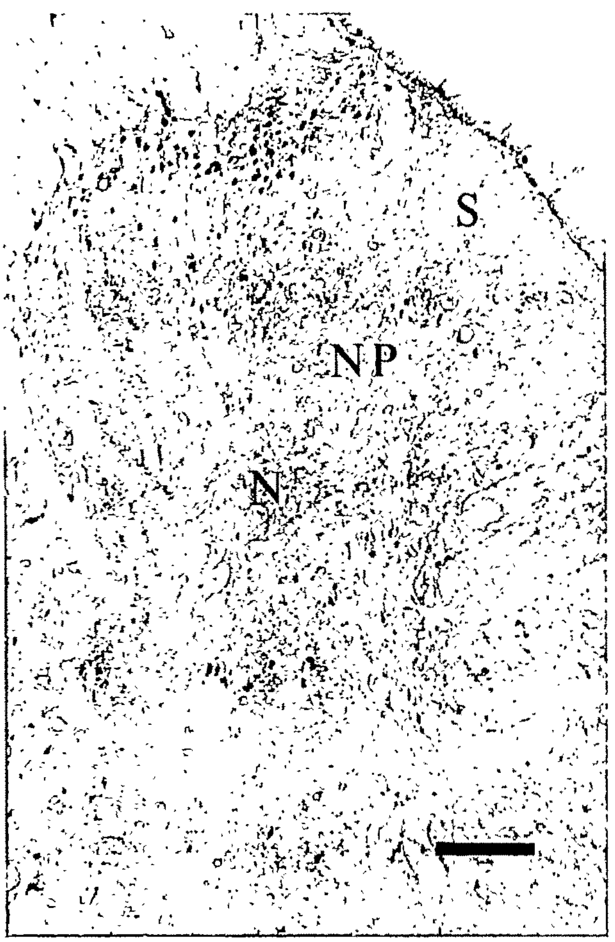

Figure 2. Fos-LI distribution in the dorsal horn of the L4 segment ipsilateral to the formalin injection in the control group. S = Superficial laminae, NP = nucleus proprius, N = neck of the dorsal horn. Scale bar = 100 μm.

of moderate pain (i.e. elevation of the injected paw) was expressed from 20 to 60 min. Peak pain score occurred 30 min after injection (fig. 1A). In rats receiving fentanyl, or nitrous oxide or halothane, or both, behaviours such as elevation, biting, shaking and flinching of the injected paw were absent during the early phase. Most rats recovered from inhalation anaesthesia, as shown by responding to painful pinch stimulation within 5 min after anaesthesia, and this was followed by a quiescent period, that is a period without any characteristic pain behaviour. Steady gait and investigatory behaviours (e.g. rearing) persisted for 10–15 min and were followed by a short period of shaking and biting of the injected paw. For rats receiving fentanyl 100 μg kg^{-1}, a variable degree of rigidity was observed on formalin injection and maintained for approximately 30 min thereafter with attenuated behavioural hyperalgesia.

Summations of the pain scores from various time intervals were compared to investigate the overall behavioural response to the formalin test (fig. 1B). At the 5–60-min interval, the score for the nitrous oxide group was identical to that for the control group, while scores for fentanyl (24 %, $P < 0.01$), halothane (18 %, $P < 0.05$), and nitrous oxide–halothane groups (17 %, $P < 0.05$) were significantly lower. Starting from 20 min after injection, summed scores for all gas groups were indistinguishable ($P > 0.05$), indicating that inhalation anaesthesia attenuated pain scores for 20 min after injection. The score for the fentanyl group was 19 % less than the control score ($P < 0.05$) at the 20–60-min interval, whereas no difference for all groups was found at 30–60, 40–60 and 50–60 min. Despite full recovery, many rats fell asleep for the rest of the time. With the injected paw held dorsiflexed tonically, the rats lay on the uninjected side to avoid accidentally touching the ground.

Ratio of Fos-LI labelled neurones in experimental groups to control group plotted at each lamina: I/II = superficial laminae, III/IV = nucleus proprius, V = neck of the dorsal horn. ▨ = Nitrous oxide 75 %, ▩ = 2 % halothane, ■ = 75 % nitrous oxide with 2 % halothane and □ = fentanyl 100 μg kg^{-1}. * $P < 0.05$, ** $P < 0.01$ compared with control.

COUNTING OF FOS-LI LABELLED NEURONES

Fos-LI labelled neurones were distinguished readily by their dark blue nucleus and scant staining of the cytoplasm. In control rats injected with 1 % formalin, numerous Fos-LI labelled neurones were observed in the superficial laminae and neck of the dorsal horn. These neurones were concentrated exclusively on the side ipsilateral to the injected paw. The most dense concentration of Fos-LI neurones, 48.3 (6.5) per section, occurred in the superficial laminae (fig. 2). Modest numbers of labelled neurones were observed in the neck of the dorsal horn, 19.4 (6.5) per section. Fewer Fos-LI neurones, 8.9 (3.2) per section, were observed in the nucleus proprius. Fos-LI labelled neurones in the negative control rats were found occasionally (less than 5 per section) suggesting that inhalation anaesthesia *per se* failed to enhance c-*fos* expression. Significant differences were evident across the five groups ($P < 0.05$), and across spinal cord laminae ($P < 0.01$). These differences were the result of a pronounced decrease in the fentanyl group. Fentanyl reduced overall numbers of Fos-LI labelled neurones (56 % of control, $P < 0.05$). Suppression of Fos-LI occurred in the superficial lamina (61 % of control, $P < 0.05$), nucleus proprius (46 % of control, $P < 0.05$) and the neck (39 % of control, $P < 0.01$) (fig. 3). None of the rats receiving inhalation anaesthesia had reduced numbers of Fos-LI labelled neurones ($P > 0.05$).

Discussion

We have demonstrated that inhalation anaesthesia with 75% nitrous oxide or 2% halothane, of both, failed to suppress formalin-induced behavioural hyperalgesia in the late phase (20–60 min after injection) and the expression of *c-fos* proto-oncogene, a molecular index of spinal sensitization to pain. Both behavioural and biochemical evidence demonstrated a lack of pre-emptive analgesic effect of inhalation anaesthesia at 0.5–1.5 MAC. Our results clearly contradict previous studies showing a modest reduction in late phase behavioural hyperalgesia using the same experimental paradigms but with a lower anaesthetic potency (30–75% nitrous oxide, 0.7–1.8% halothane, 1–2.5% isoflurane) [4–6]. The major difference between previous studies and ours is the behavioural index used to quantify formalin-induced hyperalgesia. Abram and Yaksh [4] and Goto, Marota and Crosby [6] counted the occurrence of flinch behaviour, whereas a mean rating score was used in our study. Although flinch is generally believed to be more robust and spontaneous [22], none of these studies compared flinching with mean rating score. Moreover, the stability and reliability of these behavioural measurements have never been proved under general anaesthesia. In the present study, we have shown the limitation of using behavioural observation to detect antinociceptive effect by inhalation anaesthesia. For a similar degree of suppression of behavioural response, fentanyl reduced the number of Fos-LI labelled neurones whereas inhalation anaesthesia did not. Thus, attenuation of formalin-induced behavioural hyperalgesia may occur as a result of analgesic in addition to non-analgesic effects.

The reason why we used a mean rating score was because of variable responses in previous studies that used flinch behaviour. Abram and Yaksh [4] demonstrated a modest reduction in the late phase whereas no decrease was found by Goto, Marota and Crosby [6]. Furthermore, Goto, Marota and Crosby showed that 0.9% halothane suppressed early phase flinch only partially whereas O'Connor and Abram demonstrated that 0.7% halothane completely suppressed it [5]. These results, together with ours, are a clear demonstration of how behavioural observations can vary markedly whether or not a similar variable is used. Mean rating score was thus chosen by us to avoid further confusion. One possible explanation of the discrepancy between previous studies and ours is the occurrence of flinch that may be more susceptible to prolonged amnesia after 25 min of exposure to 0.5–1.5 MAC of anaesthesia. It has been shown that single-variable measures of formalin-induced nociceptive behaviours, such as flinching or licking, are likely to be influenced by pharmacological agents which either stimulate or depress locomotor activity or cause competing stereotypic behaviours [23]. Although no residual anaesthetic effect was present during the late phase, many rats remained asleep despite full recovery from anaesthesia, as shown by painful pinch. It is unlikely that the hypnotic property of inhalation anaesthesia outlasts its anaesthetic property. Hence, potentiation of the normal sleep cycle during observation (10:00–16:00) may explain the cause of prolonged sleep. However, the lingering effect of residual gases on flinch is not supported by Abram and Yaksh [4] who found that continuous exposure to 0.25% isoflurane during the late phase failed to reduce flinch responses. This, again, does not explain the pre-emptive analgesia effect of 75% nitrous oxide (0.5 MAC) and not 0.9% halothane with or without 75% nitrous oxide (0.5–1 MAC), became nitrous oxide is less soluble in blood and so should have less of an effect in rats. Another explanation for our results is the use of a different concentration of formalin; 1% compared with 5% in previous studies. It has been shown that some behavioural responses, for example flinching and licking, are more common after 5% formalin [24]. Thus to use flinch as a dependent measure in a rat model, one must use a high concentration of formalin (5%) to obtain a meaningful level of response. However, this is inconsistent with the recent understanding that low formalin concentrations (0.5–2.5%) have the advantage of increasing the sensitivity of the test [7]. Detection of the effect of weak analgesics is facilitated by eliminating the problem of a ceiling effect, and it is furthermore possible to detect a state of hyperalgesia [17, 25]. We believe 1% formalin is more sensitive than 5% in detecting the weak, if any, analgesic effect of general anaesthesia.

A potential advantage of Fos-LI is its usefulness in determining the most appropriate times for comparison. Pain scores for all treatment groups were significantly less than for the control within 20 min after injection (i.e. 5–60 and 10–60 min, respectively). However, scores for all anaesthetics were indistinguishable after 20 min (i.e. 20–60, 30–60, 40–60 and 50–60 min, respectively). As no suppression of Fos-LI was found for rats receiving inhalation anaesthesia, we suggest that the behavioural response within 20 min after anaesthesia should be disregarded. It makes no difference if a brief period (e.g. 50–60 min) or a longer period (e.g. 20–60 min) is used. On the other hand, fentanyl produced suppression of the late phase response within 30 min after injection but no suppression thereafter. Comparison of its antinociceptive effect must therefore include the initial response (e.g. 5–60, 10–60 and 20–60 min). Thus, the behavioural response at the 20–60-min time period, a significantly lower pain score by fentanyl, and an identical score by all anaesthetic gases, are comparable to the molecular index of spinal sensitization. Despite the fact that behavioural responses to formalin test and postoperative pain vary greatly with time, potential bias from selecting an appropriate time interval for comparison is overlooked by most investigators. Various times between 5 and 75 min after injection are chosen, for example, 10–60 min (Abram and Yaksh [4]) and 30–75 min (Goto, Marota and Crosby [6]). No comparative study has been performed to explain how the specific times were chosen. Using Fos-LI as a molecular correlate of behavioural hyperalgesia, this is the first study to describe why and how the specific times were chosen.

Despite being used extensively as a quantitative tool for nociception, the physiological role of the c-*fos* gene product in the spinal cord dorsal horn remains to be determined. c-*fos* expression in the neurones is produced by either noxious or non-noxious stimulation. Non-noxious stimuli, such as brushing and manipulation of the hindlimb, evoke a moderate increase in Fos-LI in areas of the spinal cord (laminae III/VI) that receive primarily non-nociceptive afferents [26]. Without nociceptive input, walking on a rotating rod produces a large increase in Fos-LI and c-*fos* mRNA level, while the pattern of labelled neurones is distinct from that produced by noxious stimulation [14]. Under controlled stimulus conditions, it is well documented that the pattern of Fos-LI distribution is related to nociception [27]. However, non-noxious stimulation (e.g. itching) can also evoke a similar pattern of c-*fos* expression [28]. Hence, the use of biochemical markers for pain measurement must be strictly designed and carefully evaluated. Furthermore, c-*fos* expression is a result of temporal summation over time. Lack of resolution at any specific time point may greatly limit the use of this method. We suggest that c-*fos* expression should never replace behavioural observation in pain assessment. Instead, it should be accepted as a useful adjunct to behavioural observation when correctly designed.

In summary, both our molecular and behavioural indices demonstrated that pre-emptive analgesia was *lacking* after inhalation anaesthesia, regardless of gas and anaesthetic potency. Our study failed to confirm previous findings that isoflurane [4], halothane [5] and nitrous oxide [6] produced moderate pre-emptive analgesia, and thus in turn supports the hypothesis that general anaesthesia fails to block the afferent signals set off during intense surgical pain. The differential Fos-LI response between fentanyl and general anaesthesia suggests that suppression of behavioural hyperalgesia may occur as a result of analgesic and non-analgesic effects. Thus behavioural response as an index for nociception must be evaluated carefully during and immediately after general anaesthesia. We suggest c-*fos* expression is a useful adjunct to pharmacological tests whenever behavioural observation is questionable or unobtainable.

Effects of morphine on atrial preparations obtained from non-failing and failing human hearts

F. LLOBEL AND M. L. LAORDEN

Summary

We have examined the effects of morphine in auricular myocardium from non-failing and failing human hearts. In both preparations morphine induced inhibition. These responses were not antagonized by naloxone. Comparison of mean IC_{30} values obtained in non-failing (3.9 (SEM 0.2) $\times 10^{-8}$ mol litre^{-1}) and failing (5010 (200) $\times 10^{-8}$ mol litre^{-1}) hearts indicated that the morphine concentration–response curves were significantly ($P < 0.001$) shifted to the right in preparations from failing hearts. In addition, a decrease in the maximal response was observed. These data indicate that opioid receptors are not involved in the cardiac effects induced by morphine and that there is a decrease in responses to morphine in the failing heart. (*Br. J. Anaesth.* 1996; **76**: 106–110)

Key words

Heart, isolated preparation. Heart, myocardial function. Analgesics opioid, morphine.

It has been demonstrated that morphine induces negative inotropic and chronotropic effects on isolated left and right atria of the rat [1–3]. However, it has also been shown in different heart muscle preparations from mammalian species, including humans, that morphine fails to influence cardiac function directly [4]. Despite numerous studies, the possible mechanism involved in the cardiac inhibitory effects of this drug are controversial. Recently, it has been postulated that opioid agonists have complex cardiovascular actions. Some effects may be mediated via opioid receptors while others are independent of opioid receptors [5].

On the other hand it is known that the opioid system is involved in various stress situations such as shock [6] and heart failure [7]. Thus in acute heart failure patients, the β-endorphin, met-enkephalin, and dynorphin plasma concentrations are increased, which provides evidence of activation of the opioid system [8]. However, in patients with chronic heart failure, plasma concentrations of β-endorphin and lipotrophin are decreased, which is interpreted as exhaustion of the opioid system [9].

Despite the well known fact that opioids play a significant role in heart failure, there is little information on the cardiac action of morphine on the human heart, and no information on its effect in the failing human myocardium. Heart failure results in increased sympathetic drive with increased plasma noradrenaline concentrations [10]. Prolonged exposure of a cell to a drug usually results in reduction or down-regulation of functional cell surface receptor molecules. The mechanisms involved in receptor desensitization have been studied most extensively for the β adrenoceptor [11]. We have examined, therefore, if the failing heart alters responses to morphine, as occurs with β adrenergic agonists. Thus we have investigated the effects of morphine in isolated human right atrium from failing and non-failing human hearts and any possible involvement of opioid receptors by undertaking similar experiments in the presence of naloxone.

Materials and methods

PATIENTS

The study was approved by the Institutional Research Practices Committee. All patients gave written informed consent. The Committee of Human research also approved the study.

Human right atrial appendages were obtained from 20 patients (12 male) without apparent heart failure (mean age 50.1 (range 36–58) yr) with mitral valve disease (NYHA classes I–II). Myocardium from failing human hearts was obtained from 20 patients (14 male) (mean age 52.8 (range 40–69) yr) with severe mitral valve disease (NYHA classes III–IV). In all patients auricular muscle was obtained from tissue resected during cardiac surgery before heart cannulation preceding extracorporeal circulation. None of these patients had been treated with sympathomimetic drug or β adrenoceptor antagonists for at least 3 weeks before operation. Some patients were treated with nitrates (15), calcium antagonists (10) or diuretics (15), and occasionally with angiotensin-converting enzyme (ACE) inhibitors ($n = 8$) or digitalis glycosides ($n = 3$), alone or in combination.

General anaesthesia comprised fentanyl with benzodiazepines and isoflurane. Pancuronium was used as a neuromuscular blocker (the washout procedure described below was designed to eliminate any potential influence of these agents).

Immediately after excision, the atrial muscle strips were placed in ice-cold pre-aerated Tyrode solution (for composition see below) and delivered to the laboratory within 15 min.

PREPARATION OF TISSUES AND ORGAN BATH EXPERIMENTS

The right atrial appendages were dissected to yield trabecula strips (4–5 mm in length and 1 mm or less in diameter) without endocardial damage and with fibres running parallel to the length of the strip.

The preparations were mounted in 10-ml organ baths at 37 °C containing a modified Tyrode's solution of the following composition (mmol litre^{-1}): NaCl 119.8; $CaCl_2$ 1.8; KCl 5.4; $MgCl_2$ 1.05; NaH_2PO_4 0.42; $NaHCO_3$ 22.6; glucose 5.05; ascorbic acid 0.28; and disodium EDTA 0.05. The bathing solution was aerated with 95 % oxygen and 5 % carbon dioxide. Myocardial strips were stimulated electrically (Grass SD-9) by two platinum ring electrodes at a frequency of 1 Hz by rectangular pulses of 10 ms and supramaximal voltage (30 V). Each preparation was suspended under a resting tension of 0.5 *g*. After suspension in the organ baths, the tissues were washed four times every 10 min. Thereafter the preparations were allowed to equilibrate for 90 min and the bathing solution was changed once after 45 min. Isometric force of contraction was measured using a force displacement transducer (Grass FT-03) and recorded on a Dynograph Beckman polygraph. Each muscle preparation was used for one concentration–response curve.

Increased concentrations of morphine were added cumulatively to the organ bath at concentrations ranging from 10^{-10} to 10^{-3} mol litre^{-1}. Each drug concentration was added to the organ bath in a volume of 0.1 ml at 5-min intervals. Concentration–response curves to morphine were obtained also in the presence of naloxone (10^{-8}, 10^{-7} or 10^{-6} mol litre^{-1}) added 15 min before morphine. Concentration–response curves were also constructed with naloxone 10^{-11}–10^{-4} mol litre^{-1} (data not shown). In the time-control groups, equal volumes of distilled water (diluent for morphine and naloxone) were added to the tissue baths at the same times as those for the morphine and morphine with naloxone groups. To evaluate heart failure, we also constructed concentration–response curves with isoproterenol 10^{-11}–10^{-5} mol litre^{-1} in preparations from non-failing and failing hearts.

The effects of morphine alone and isoproterenol are expressed as percentage change from baseline values. Similarly, the effects of morphine in the presence of naloxone are expressed as percentage change from baseline values after opioid antagonists.

STATISTICS

The results are expressed as means (SEM) of *n* experiments. Statistical comparisons were performed with one-way analysis of variance, followed by the Newman–Keuls *post hoc* test. Differences with *P* values, less than 0.05 were considered significant. IC_{30}, IC_{50} and the slope were calculated by linear regression of the log concentration plot of the data with the aid of a computer program [12]. Mean slope values were compared using Student's *t* test.

COMPOUNDS

The drugs used were morphine (Alcaliber Spain), naloxone hydrochloride (Merck, Sharp & Dohme, Spain) and isoproterenol hydrochloride (Sigma, Spain).

Results

The maximal effect on force of contraction occurred within 3–4 min after adding morphine or isoproterenol to the bath. All concentrations of isoproterenol tested significantly increased the force of contraction in a dose-related pattern compared with control. The maximal effect obtained in the non-failing heart (97.2 (3.2) %) was significantly ($P < 0.01$) higher than that obtained in the failing heart (51.2 (1.1) %). Similarly, the IC_{50} for isoproterenol was significantly ($P < 0.001$) lower in non-failing compared with failing hearts (9.3 (0.2) × 10^{-8} and 120 (5.8) × 10^{-8} mol litre^{-1}, respectively). Thus isoproterenol was more potent in non-failing than in failing hearts.

There were no significant differences between the time-matched control groups obtained in non-failing and failing hearts (fig. 1). In both cases, morphine induced cardiac inhibition. In the non-failing heart, morphine significantly reduced ($P < 0.05$; $P < 0.01$; $P < 0.001$) cardiac inhibition at concentrations ranging from 10^{-9} to 10^{-3} mol litre^{-1} compared with

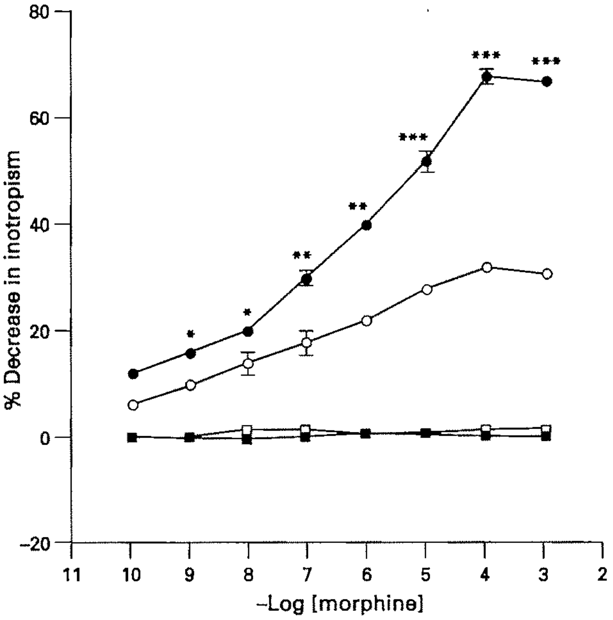

Figure 1 Concentration–response curves for morphine (●, ○) in isolated electrically stimulated human right atrial strips from non-failing (filled symbols) and failing (open symbols) hearts (■, □ = control). Average auricular inotropism (mean (SEM)) for non-failing hearts was 0.90 (0.05) *g* and 0.89 (0.02) *g* for failing hearts. $^*P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$ *vs* failing heart. Each point represents the mean (SEM) of eight experiments for each experimental group.

Morphine+Nx (10^{-6} mol litre^{-1})	34 (1.8)	6520 (190)	4.3 (0.2)	0.98	3.7	5.0

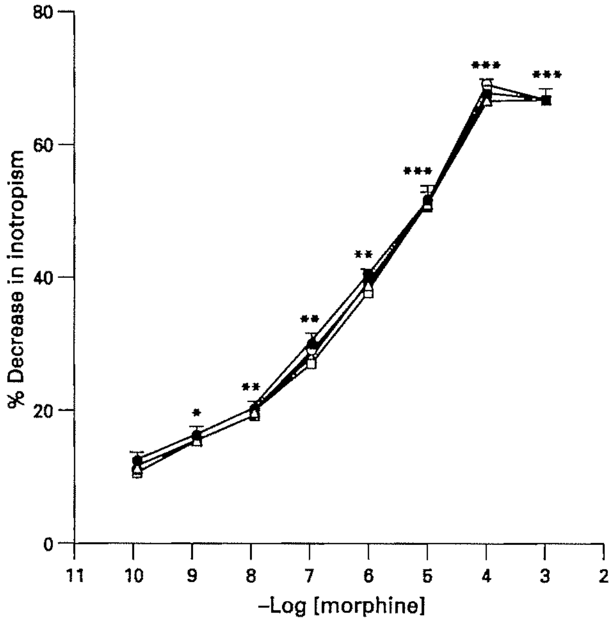

Figure 2 Concentration–response curves for morphine in isolated electrically stimulated human right atrial strips from non-failing hearts in the absence (●, $n = 8$) and presence of naloxone 10^{-8} (○, $n = 4$), 10^{-7} (△, $n = 4$) or 10^{-6} (□, $n = 4$) mol litre^{-1}. Average auricular inotropism (mean (SEM)) in the absence of naloxone was 0.99 (0.05) *g*, and 0.93 (0.05) *g*, 0.96 (0.08) *g* and 0.98 (0.05) *g* in the presence of naloxone 10^{-8}, 10^{-7} and 10^{-6} mol litre^{-1}, respectively. Each point represents mean (SEM). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$ compared with morphine alone.

the time-matched control. However, the inhibition caused by morphine was reduced in failing compared with non-failing hearts (fig. 1). Thus the maximal effect obtained by morphine (32 (1.0) %) was lower ($P < 0.001$) than that obtained in the non-failing heart (68 (1.5) %). Comparison of IC_{30} values (tables 1, 2) indicated that the morphine concentration–response curves were significantly ($P < 0.001$) shifted to the right in preparations from failing hearts (fig. 1). Thus morphine was significantly ($P < 0.001$) more potent in non-failing than in failing hearts (tables 1, 2). As illustrated in tables 1 and 2, the slope of morphine in non-failing hearts was higher ($P < 0.01$) than that obtained in failing hearts.

To determine if the effects of morphine could be attributed to activation of opioid receptors, we studied the action of this drug in the presence of naloxone 10^{-8}, 10^{-7} or 10^{-6} mol litre^{-1} on auricular strips from patients with and without heart failure. In both cases cardiac inhibition induced by morphine was not antagonized (figs 2, 3; tables 1, 2).

Discussion

The high concentrations of morphine used in this study are equivalent to those in patients given morphine for pain relief. Thus high plasma morphine concentrations (> 10^{-6} mol litre^{-1}) occur during the first minute after morphine 10 mg i.v. [13].

It has been shown that morphine, DAMGO, DPDPE and U-50,488H induced cardiac inhibition in rats [1, 14]. Similarly, morphine inhibited auricular inotropism in a concentration-dependent manner in preparations from patients without heart failure. However, the cardiac inhibitory effects of morphine obtained in isolated left atria of the rat were lower than those observed in this study. These differences may represent an intrinsic difference in excitation–contraction coupling between human and rat myocardium.

The negative inotropic effects induced by morphine in both failing and non-failing hearts were not antagonized by naloxone. Although morphine has a higher selectivity for μ receptors, at the concentrations studied it can bind to σ and κ receptors, and

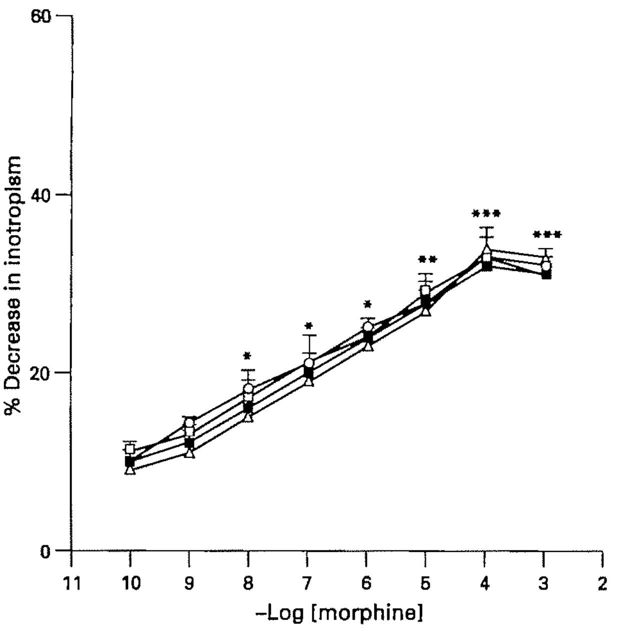

Figure 3 Concentration–response curves for morphine in isolated electrically stimulated human right atrial strips from failing hearts in the absence (■, $n = 8$) and presence of naloxone 10^{-8} (□, $n = 4$), 10^{-7} (○, $n = 4$) or 10^{-6} (△, $n = 4$) mol litre^{-1}. Average auricular inotropism (mean (SEM)) in the absence of naloxone was 0.89 (0.02) *g*, and 0.91 (0.05) *g*, 0.99 (0.03) *g* and 0.99 (0.08) *g* in the presence of naloxone 10^{-8}, 10^{-7} and 10^{-6} mol litre^{-1}, respectively. Each point represents mean (SEM). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$ compared with morphine alone.

therefore in this study we used high concentrations of naloxone to antagonize all three types of opioid receptor [15]. Our data demonstrated that opioid receptors were not involved in the inhibitory effects of morphine. Similarly, other authors [5, 16–18] have described that the cardiac effects induced by high doses or concentrations of opioids are not mediated by opioid receptor activation. If the inhibitory cardiac response induced by morphine was not mediated by opioid receptors, then other mechanisms may be considered. One possibility is that the drug may be interacting with other receptor systems known to mediate inhibitory cardiac effects, such as the muscarinic receptor system; if so the muscarinic antagonist, atropine, should have eliminated this effects. However, previous studies in our laboratory have demonstrated that atropine failed to modify the negative inotropic and chronotropic effects induced by opioid agonists in isolated cardiac tissues [17, 18], thus excluding the involvement of muscarinic receptors.

An earlier investigation [19] demonstrated an interaction between the opioid and adrenergic systems in spontaneously beating guineapig atria. Opioids inhibited the cardiac response to adrenergic stimulation in both atrial and ventricular preparations [20–22]. Therefore, another possible explanation for the inhibitory effects of opioids in these studies is presynaptic inhibition of the sympathetic nervous system. Thus a previous study in our laboratory showed that the negative inotropic effect induced by opioids in left atria of the rat was not apparent in the presence of reserpine [17]. Furthermore, this response to opioid agonists was dependent on β adrenergic mechanisms as it was eliminated by prior block with propranolol [17].

Thus our data and the studies of others described above demonstrate that the negative inotropic action of morphine on the heart is mediated by a non-opioid mechanism and suggest that an adrenergic mechanism may be involved.

We have also demonstrated for the first time that the negative inotropic response to morphine was decreased markedly in heart failure. Thus the concentration–response curve for morphine was shifted to the right and the maximum inhibition to morphine was decreased in failing hearts. Changes in the concentration–response curves for opioid agonists, such as horizontal position, maximum effect and slope, may involve alterations in the affinity of the receptor for the agonist, the density of opioid receptors or the efficacy of the drug–receptor interaction [23]. However, our data clearly demonstrated that the inhibitory cardiac response to morphine was not mediated by opioid receptors, which leads to the conclusion that the decrease in negative inotropic response to opioids in failing hearts could not be explained by changes in the density or affinity of opioid receptors.

It is known that heart failure is characterized by profound β adrenergic receptor desensitization in the myocardium, apparent as depressed inotropic responsiveness to β adrenergic agonists [24, 25], mediated by several disorders in β adrenergic receptor signalling [26, 27]. Abnormal myocardial β adrenergic signal transduction is characterized by selective β_1 receptor downregulation [11, 28, 29]. Our data are in agreement with these studies. Thus the positive inotropic effects induced by isoproterenol were decreased in the failing heart. Moreover, isoproterenol was more potent in the non-failing compared with the failing heart.

Another explanation for the inhibitory cardiac effects of opioids is interaction at the level of the post-receptor transduction cascades. It has been demonstrated that β adrenoceptor-sensitive adenylate cyclase is inhibited by μ opioid agonists in rat striatal neurones [30]. In addition, opioid agonists and antagonists potentiate the cardiac effect of β adrenergic agonists by a mechanism unrelated to the binding of these drugs to opioid receptors [31]. Moreover, propranolol antagonized the pressor effects of [met]enkephalyl Arg^{6}-Phen^{7} in the anaesthetized rat [32] and the excitatory effects of morphine on ventricular automaticity [33] while potentiating the negative chronotropic effects of U-50,488H [20]. In addition, naloxone potentiated the cardiovascular responses to sympathomimetic amines [34]. These studies support the concept that a β adrenergic mechanism could be involved in the cardiac effect of opioids. If an interaction between opioid agonists and β adrenergic receptors were responsible for the negative inotropic response to morphine obtained in our preparations, the decrease in the inhibitory cardiac response to morphine obtained in the failing heart could be explained by selective β_1 adrenoceptor downregulation that occurs in heart failure.

A perfusion system for *in vitro* measurement of human cilia beat frequency†

D. A. SELWYN, A. GYI, J. H. RAPHAEL, A. KEY AND J. A. LANGTON

Summary

We have designed and built a perfusion system and perfusion chamber to allow investigation of the effects of anaesthetic agents on human cilia *in vitro*. Using this system, samples of human respiratory cilia can be maintained in a stable and controlled environment for several hours. We measured cilia beat frequency of nasal respiratory epithelium from 10 healthy volunteers; cilia beat frequency was constant over a 4-h period, and measurements were found to be in good agreement with previously published work [1]. In a separate study we investigated the effect of a sleep dose of propofol on cilia beat frequency in samples from six patients undergoing minor surgery; samples were obtained before and immediately after induction of anaesthesia with propofol 2–3 mg kg^{-1}. There was no statistically significant difference in cilia beat frequency between data obtained before and after induction with propofol. (*Br. J. Anaesth.* 1996; **76**: 111–115)

Key words

Anaesthetics i.v., propofol. Lung, trachea. Equipment, perfusion system.

After routine surgery, impairment of respiratory epithelial cilia function may predispose patients to develop areas of atelectasis and postoperative chest infection; the overall incidence of chest infection after upper abdominal surgery may be as high as 20% [2]. It has been demonstrated that volatile anaesthetic agents cause a decrease in mucus transport rate [3] which is an important host defence mechanism. Respiratory epithelial cilia have a beat cycle which is specialized to facilitate transport of mucus and inhaled particles to the oropharynx, where they may be swallowed or expectorated. Mucus transport rate is dependent on the interrelationship between cilia beat frequency (CBF) and the viscoelastic properties of mucus [4, 5]. A previous pilot study from our laboratory has shown that halothane has a significant depressant effect on CBF [6], but the mechanism of this effect is not known.

In order to study the effects of anaesthetic agents on human respiratory epithelial cilia in a controlled environment, it was necessary to build a new perfusion chamber, as chambers described previously did not satisfy our requirements for the investigation of anaesthetic agents. This new perfusion chamber enabled us to investigate the survival of respiratory cilia *in vitro* and the effect of repeated measurements of CBF.

Materials and methods

PERFUSION CHAMBER

The perfusion chamber was constructed from aluminium in two halves, with an integral perfusion channel that allowed fluid exchange (fig. 1). The cilia sample was placed between a lower fixed cover slip and an upper removable cover slip. The upper cover slip was manufactured specially with a diameter of 45 mm and was sealed using a silicone impregnated rubber washer. It is this large cover slip which allows a wide plane of movement by the microscope objective lens. The chamber depth was 0.85 mm, producing a small internal volume of 1.1 ml.

Cilia beat frequency has been shown to be dependent on temperature [9] and therefore the perfusion system incorporated several features to maintain a constant temperature. The perfusate was kept in a heated water bath maintained at 40 °C. The perfusion channels upstream of the chamber passed through a countercurrent water jacket maintained at 40 °C. The chamber incorporated an integral thermostatically controlled heating element set to 37 °C (fig. 2). The system was calibrated with a thermocouple located in the middle of the external surface of the cover slip and the measured temperature varied by ±0.1 °C. The whole chamber was closed with an annular threaded screw and a composite locking device.

The cilia sample was perfused with Hanks balanced salt solution (HBSS, Gibco, Life Technologies) from an aerated reservoir. This was connected to the chamber using metallic tubing. The medium reservoir was maintained at a height of 25 cm above the microscope stage to allow gravity feed of the medium at a rate of 0.5 ml min^{-1}. A calibrated photometric drip counter enabled a constant flow rate to be maintained.

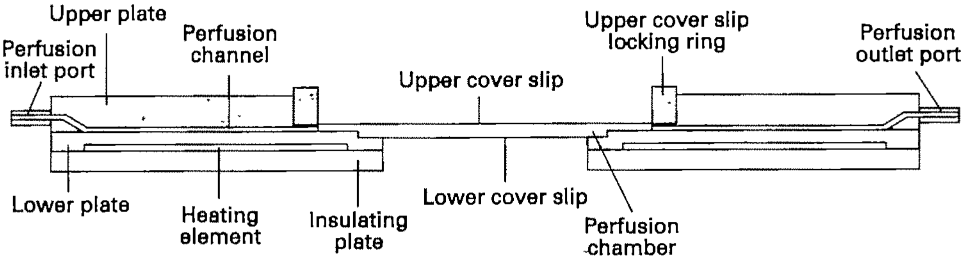

Figure 1 Section through the perfusion chamber.

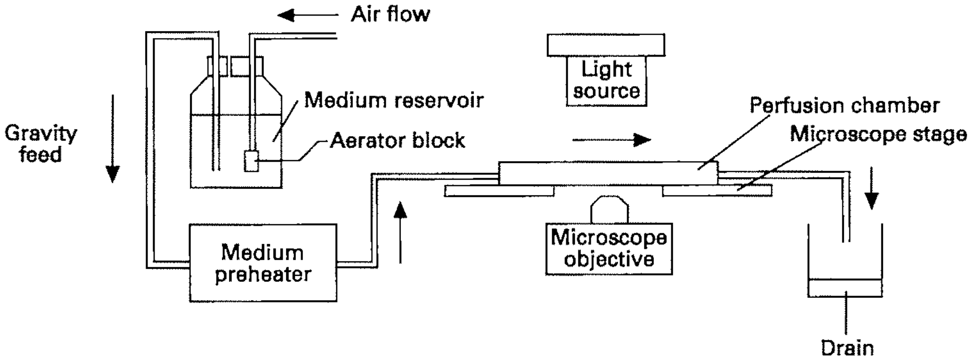

Figure 2 Schematic diagram of the cilia perfusion system.

MEASUREMENT OF CILIA BEAT FREQUENCY

CBF was measured using a television–video modification of the transmitted light technique described originally by Teichtahl, Wright and Kirsner [7]. This technique uses a pinhole photodiode placed against a television image of ciliated epithelium. Movement of the beating cilia across the photodiode produces a characteristic signal which can be viewed on an oscilloscope before a 15-s sample is downloaded to a 386 sx computer (Dell Computer Corporation, Bracknell, UK). Having undergone low-pass filtering (25 Hz) to reduce interference, the signal was sampled at 200 Hz by an analogue to digital converter, stored and displayed. The signal was then processed using mathematica 2.2 software (Wolfram Software, USA) to produce a power spectrum using fast Fourier transforms. CBF was taken as the peak of the power spectrum.

After specimens of cilia were loaded into the perfusion chamber, two readings were obtained from as many edges as possible during a 20-min sampling period, edge selection criteria being those described previously [6]. In summary these comprised: measurements made only from free edges of ciliated epithelium; the edge of the epithelium must not be disrupted and it must be greater than 60 µm in length; the edge must not be contaminated with mucus deposits; and single cells and cell groups partially denuded of cilia were not included.

The samples were viewed under a high resolution (×600) microscope (Nikon Diaphot), using the Normaski polarized light technique. The image obtained from the microscope was transmitted to a high resolution video monitor and recorded onto videotape. CBF was measured at hourly intervals for 4 h.

Table 1 Exclusion criteria for volunteers or patients recruited for measurement of cilia beat frequency

History of asthma, hay fever or atopy.
History of smoking or cessation of smoking within the past 2 yr.
History of upper respiratory tract infection within the preceding month.
History of coagulation or bleeding diathesis.
History of cystic fibrosis, bronchiectasis or documented cilia motility problems.

VALIDATION OF CHAMBER PERFORMANCE

To study the time taken for drug concentrations to change within the chamber and to ensure that flow streaming did not occur, we perfused the chamber with HBSS at a steady rate through a chamber mounted on a light box. Photographs were taken at 30-s intervals from a camera (Pentax UK Limited) at a fixed height (41.5 mm) above the light box using a shutter speed of 1/15 s with an aperture of f11 on to ISO 100 film (Kodak Limited, USA). After a 2-min stabilization period, the perfusate was changed to HBSS containing a known concentration of Dylon ivory black dye. After 5 min the perfusate was changed back to HBSS only. The change in dye colour or wash-in effect was analysed using a densitometer (LKB, Bromma), performing a line density plot at three cuts across the chamber photographs; an inlet cut, a central cut and an outlet cut.

CILIA SURVIVAL EXPERIMENTS

This study was conducted in two parts. In the first part of the study, after obtaining Ethics Committee approval and written informed consent, we recruited 10 healthy volunteers (mean age 28.8 yr). All volunteers satisfied our admission criteria (table 1). Nasal sampling is a relatively painless procedure which does not require local anaesthesia. In all cases the method of sampling was identical and we used a small wire bronchoscopy brush to scrape ciliated epithelium from the inferior nasal turbinate or anterior nasal wall, having previously wetted the sample brush in HBSS. The sample obtained was placed immediately into Hanks nutrient medium at room temperature before being transferred to the perfusion chamber within 1 h.

In the second part of the investigation and after obtaining Ethics Committee approval and written informed consent, we recruited six unpremedicated ASA I patients, undergoing removal of wisdom teeth under general anaesthetic. Nasal sampling, as previously described, was performed immediately before induction of anaesthesia and again after a sleep dose of propofol 2–3 mg kg^{-1}. A separate wire bronchoscopy brush was used for each specimen. The samples obtained were placed into nutrient medium, at room temperature, before being transferred to the perfusion chamber within 1 h.

Baseline CBF measurements were obtained when the specimen had been placed within the chamber, and this represented time point zero. CBF readings were repeated 1 h later. The chambers were perfused with nutrient medium throughout the experiment and maintained at 37 °C (±0.1 °C).

Statistical analysis was performed using SPSS for windows v 5.01 to give analysis of variance for repeated measures using MANOVA (multiple analysis of variance). Statistical significance was taken at $P < 0.05$.

Results

VALIDATION OF THE PERFUSION SYSTEM

The results of the line density studies are shown in figure 3. The densitometer performed a vertical line density plot across the chamber at three points. The change in density of the perfusion dye (mean density, arbitrary units) was plotted against time in seconds. The smooth advancement of the wavefront can be seen in the three areas of study: the inlet of the chamber, the central portion of the chamber and the exit region. The outlet region showed a delayed time course with respect to the inlet region. The time taken for change within the chamber to plateau was approximately 160 s. There was no evidence of flow streaming or any areas of diminished perfusion.

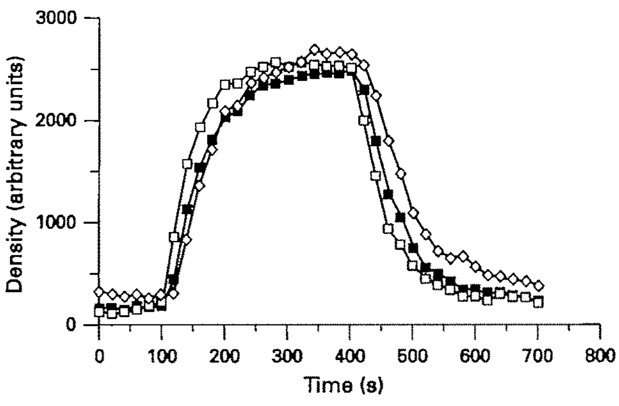

Figure 3 Change in dye concentration with time for the three cuts (inlet (□), middle (■) and outlet (◇) cuts) across the chamber.

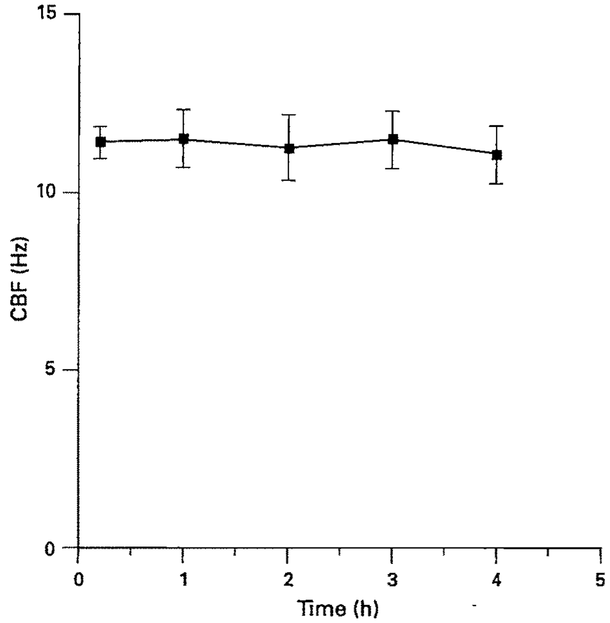

Figure 4 Cilia beat frequency (CBF) *vs* time for volunteer nasal brushings (mean, SD).

Table 2 Beat frequency (mean (SD)) in respiratory epithelial cilia before and 1 h after induction of anaesthesia with propofol

	CBF (Hz) at 1 h	CBF (Hz) at 2 h
Before propofol induction	11.38 (2.33)	11.40 (2.25)
After propofol induction	11.54 (2.17)	11.97 (1.89)

CILIA SURVIVAL EXPERIMENTS

CBF of nasal respiratory epithelium in healthy volunteers is shown in figure 4. The initial readings were taken within 1 h of the specimen being obtained. The subsequent readings were taken at hourly intervals for a total of 4 h. The cilia samples were perfused continuously with Hanks medium. Each reading represents the mean of data from 10 subjects, of which each subject had at least 10 separate readings of CBF at each time. The 15-s sampling period and mean beat frequency represents over 1500 datum points for each subject at each time.

Mean baseline CBF in the volunteer group was 11.3 (SEM 0.774) Hz. The measured CBF was shown to be constant over a 4-h time period and was in good agreement with other published work [1]. There was no statistically significant difference in CBF between the different times.

CBF for patients before and after induction of anaesthesia with propofol is shown in table 2. Time point one represents the baseline readings when the sample had been placed into the chamber and the chamber temperature had stabilized. This was within

60 min of the sample being obtained from the patient. The second time represents CBF measured 1 h later. Mean baseline CBF in the propofol group before induction of anaesthesia was 11.4 (0.93) Hz and after induction 11.7 (0.83) Hz. There was no significant difference between the two groups at each time and CBF was in good agreement with previously published work [1].

There were no anaesthetic complications caused by sampling of nasal respiratory cilia and neither the patients nor the volunteers found the sampling procedure particularly painful.

Discussion

Several factors contribute to mucociliary transport, including mucus quantity and composition, number of ciliated cells, CBF and effectiveness and coordination of cilia beating. The exact relationship between cilia activity or beat frequency and tracheal clearance rate is unclear. A good correlation between CBF and mucus transport rate (MTR) has been reported in some studies [9], whereas in others no direct relationship has been found [10]. Many of the studies investigating CBF have been performed on animal species or have used laboratory apparatus where specimens can be kept for only short periods. Consequently, we designed and validated a perfusion system which allows samples of human respiratory cilia to be kept in a stable and controlled environment for many hours while permitting reliable and repeated measurement of CBF in real time. The chamber design was based on that of Braga [11], with a number of significant improvements; our chamber had a large viewing area to permit increased microscope objective travel across the sample, and it also allowed focusing throughout the whole depth of the sample which improved sample visualization. CBF varies markedly with temperature; increasing temperature from 25 to 37 °C increases CBF by 50 % [12]. Consequently, it is important to have accurate and stable heat control. Our chamber was temperature regulated and maintained a stable sample environment by preheating the perfusate and using an integral thermostatic heating element. The chamber was completely sealed and therefore allowed accurate administration of volatile anaesthetic agents in a known and reliable concentration [13]. Earlier pilot work revealed that volatile agent was lost with plastic tubing, and therefore throughout this system we have used metallic stainless steel tubing to minimize losses.

We have shown that there was uniform flow and therefore perfusion throughout the whole chamber and also that significant flow streaming did not occur. This allowed us to be confident that cilia specimens can be maintained in optimal conditions for long periods of time and that drugs added to the perfusate system will bathe the whole sample under investigation.

We chose a 4-h measurement period to enable us to detect any delayed variation in CBF with time; during this period, cilia maintained normal beat frequencies.

Initial pilot work using a peristaltic perfusion pump produced sample movement and disruption, and was therefore abandoned in favour of a gravity feed system. We chose a perfusion rate of 0.5 ml min^{-1} as it allowed rapid change in chamber conditions without producing sample movement or disruption. Accurate flow of perfusate was ensured by the use of a calibrated photometric drip counter. With the aid of a densitometer, we showed that a change in drug concentration would be expected to equilibrate within the chamber after 160 s. The chamber was easy to assemble, robust and reliable, and easy to clean.

It is known that there are α and β receptors on ciliated epithelium. Studies have shown that autonomic neurotransmitters and neurohormones have a significant influence on mucociliary activity. The action of these neurotransmitters and neurohormones on CBF may be mediated via two different mechanisms, one involving calcium and one via cAMP [14–17]. We found that *in vivo*, after an induction dose of propofol 2–3 mg kg^{-1}, there was no measurable effect on CBF. Halothane has been shown *in vitro* to have a depressant effect on CBF [6] although the mechanism for this is not known, and further work is necessary to elucidate the exact cellular mechanisms involved.

Effects of 3 MAC of halothane, enflurane and isoflurane on cilia beat frequency of human nasal epithelium *in vitro*

J. H. RAPHAEL, D. A. SELWYN, S. D. MOTTRAM, J. A. LANGTON AND C. O'CALLAGHAN

Summary

We have measured the effects of three times the minimum alveolar concentration (MAC) of halothane, enflurane and isoflurane on cilia beat frequency of human nasal epithelial brushings from 18 healthy adult patients. Using the transmitted light technique and paired perfusion chambers, the cilia were exposed to 2.25% halothane, 5% enflurane or 3.6% isoflurane in air, or air alone, in a controlled and blinded manner. Over a 4-h observation period, cilia beat frequency of the samples exposed to inhalation anaesthetic agents demonstrated a significant reduction in frequency compared with controls exposed to air alone. Mean cilia beat frequency for the samples exposed to halothane was 9.3 (SEM 1.3) compared with its controls of 11.4 (1.0); for the samples exposed to enflurane, 10.9 (1.3) compared with its controls of 11.6 (1.2); and for the samples exposed to isoflurane, 10.8 (1.1) compared with its controls of 11.6 (1.2). There was a statistically significant difference between the samples exposed to all three volatile agents and their associated controls (halothane, $P = 0.01$; enflurane, $P = 0.03$; isoflurane, $P = 0.01$; nested repeated measures analysis of variance utilizing polynomial contrasts). (*Br. J. Anaesth.* 1996; **76**: 116–121)

Key words

Anaesthetics volatile, halothane. Anaesthetics volatile, enflurane. Anaesthetics volatile, isoflurane. Lung, trachea.

Respiratory infections are a major cause of morbidity after surgery and are particularly common following upper abdominal surgery and in smokers [1]. Despite different anaesthetic techniques, the incidence of postoperative chest infections has remained unchanged over the last 50 yr, ranging from 14 to 21 % for upper abdominal surgery [1–4]. A recent study also demonstrated an increase in mean hospital stay from 7.8 to 10.7 days in those patients developing a postoperative chest infection [1].

There is a predisposition to development of postoperative chest infections in atelectatic regions of the lung where secretions are retained [5]. In clinical practice most emphasis has been placed on promoting mucus clearance by encouraging coughing through improved analgesic regimens; however, the most important natural defence against chest infection is the mucociliary transport system.

Mucus transport depends on the volume and physical properties of the mucus and on the function of the beating cilia. The depressant effects of anaesthetic agents on mucus transport are well established [6–8]; however, the effects of anaesthetic agents on ciliary function have received little attention. In a pilot study, we have recently documented the depressant effect of halothane on human respiratory cilia beat frequency [9].

We have developed a system to expose human ciliated tissue to known concentrations of volatile anaesthetic agents and measure cilia beat frequency in a controlled and blinded manner [10]. With this system we have investigated the effects of 3 MAC of halothane, enflurane and isoflurane on human respiratory cilia beat frequency.

Patients and methods

After obtaining Ethics Committee approval and informed patient consent, we obtained samples of ciliated epithelium from 18 non-smoking healthy patients, eight male, mean age 34.3 (range 22–78) yr, who were not receiving any medications and had not suffered an upper respiratory tract infection within the previous 4 weeks. The patients were unpremedicated.

In a separate study we demonstrated that a single induction dose of propofol had no effect on cilia beat frequency measured subsequently *in vitro* [10]. After an induction dose of propofol 2–3.3 mg kg^{-1}, samples of ciliated respiratory epithelium were obtained by passing a bronchoscopy brush over the inferior nasal turbinates. The brush was agitated in Hanks buffered salt solution (HBSS) to remove the tissue from the brush.

To investigate the effects of the volatile anaesthetic agents on the cilia we designed and built a perfusion system [10]. This comprised two perfusion chambers to house the ciliated tissue from one individual, each consisting of an aluminium block with integral channels at two sides and with reversibly sealed coverslips at the top and bottom. Each chamber was perfused using metallic connecting tubing passing from a separate delivery bottle of HBSS into the

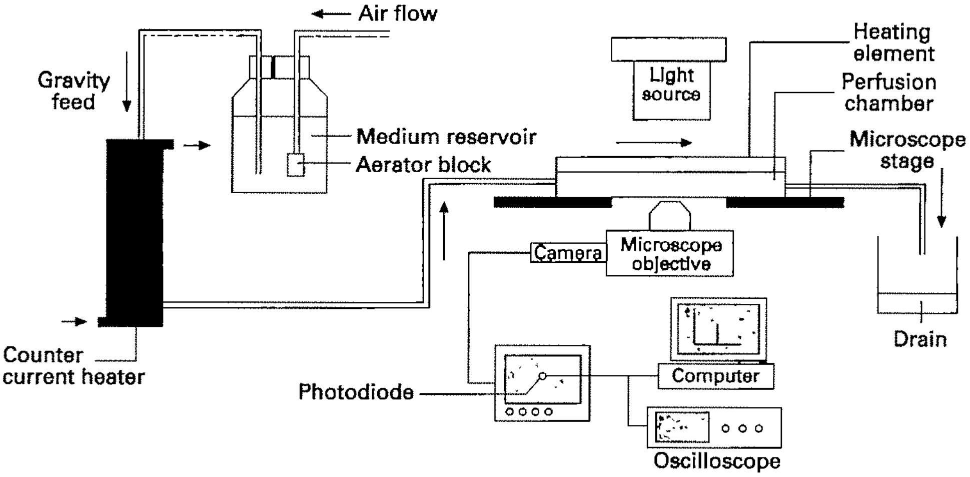

Figure 1 Perfusion system for the *in vitro* measurement of cilia beat frequency.

entry port of the chamber and out from its exit port through plastic connecting tubing into a collecting beaker. The chambers were perfused with HBSS under the effect of gravity at 0.5 ml min^{-1}. Air 1000 ml min^{-1} was either passed directly into one of the bottles of HBSS or passed through a Tec 3 vaporizer before passing into the other bottle. This divergence was achieved in a manner by which the observer was blinded as both metallic delivery tubes were wound around one another within a counter-current water jacket. The outputs from the three Tec 3 vaporizers for halothane, enflurane and isoflurane with an air flow of 1 litre min^{-1} were calibrated using an analyser (Capnomac, Datex).

The bottles of HBSS were immersed in a water bath at 37 °C that also flowed through the counter-current heat exchanger surrounding the metallic delivery tubing. The perfusion chambers were heated to 37 ($\pm$0.1) °C by means of a thermostatically controlled heating element mounted on the underside of the chamber (fig. 1).

To confirm the ability of the system to successfully deliver volatile agents to the chamber, we used halothane as a test agent. We set a calibrated Fluotec 3 vaporizer to 4% and allowed 15 min for equilibration. We sampled the perfusate from the reservoir bottle by aspirating with airtight syringes and obtained samples downstream of the perfusion chamber by attaching the syringes to a T-piece. The samples were extracted into known quantities of n-heptane. These samples were then analysed by gas chromatography (Perkins Elmer 8410) with a DB-17 column, using helium as the carrier gas and detection by flame ionization standardized for halothane [11].

Analysis of cilia beat frequency was performed using a modification of the transmitted light technique that most closely resembles that described previously by Teichtahl, Wright and Kirsner [12]. This method detects ciliary movement by their interference with a light beam which is transduced from the voltage changes of a photodiode and processed mathematically to give a power spectrum of the frequencies produced by ciliary beating. Samples of ciliated epithelium from a patient were mounted between the coverslips of two paired chambers. These were connected to the bottles containing the HBSS perfusate with one bottle receiving the volatile agent in air and the other air alone. When the chambers had equilibrated to 37 °C as indicated by the temperature plate on the chamber base, measurements of cilia beat frequency were commenced. Acceptable ciliated edges for measurement were defined as those devoid of mucus and at least 60 µm long. Measurements were not taken from individual cells or disrupted edges.

Six patient samples were exposed to each of the volatile agents studied and readings were taken from both chambers before exposure to the volatile agent and then at 1, 2 and 3 h after one chamber was exposed to the volatile agent and the other continued to be exposed to air alone. The vaporizer was set at a concentration of 3 MAC for unpremedicated young adults at 37 °C. This represented 2.25% for halothane, 5% for enflurane and 3.6% for isoflurane. We analysed as many acceptable ciliated edges as possible from a minimum of six to a maximum of 10 from each chamber in each defined time band.

STATISTICAL ANALYSIS

The mean of the peak cilia beat frequencies from the power spectrum was computed for each sample at each time. The nested data were analysed by repeated measures analysis of variance (SPSS for windows v5.01). As the effects of volatile agents over time on cilia beat frequency are unknown, we used polynomial contrasts. Significance was taken at $P < 0.05$.

Results

HALOTHANE GAS CHROMATOGRAPHY

Measurements from the gas chromatograph indicated that there was no significant loss of the test volatile agent during perfusion through the system (table 1). From the measured aqueous concentrations of halothane in the delivery bottle and downstream of the perfusion chamber, the equivalent concentrations (in % atm) were calculated and the estimated delivered concentrations were derived from a standard curve and were equivalent to 3.62% (95% confidence intervals (CI) 3.02 to 4.22) for the

Table 1 Mean (SEM) halothane concentrations in the delivery bottle and downstream of the perfusion chamber during exposure to 4% halothane

	Delivery bottle ($n = 4$)	Downstream of chamber ($n = 7$)
Aqueous concn (μmol litre^{-1})	785 (56.2)	933.4 (120.5)
Equivalent concn (% atm)	2.79 (0.2)	3.32 (0.43)
Estimated delivered concn (% atm)	3.62 (0.3)	4.3 (0.55)

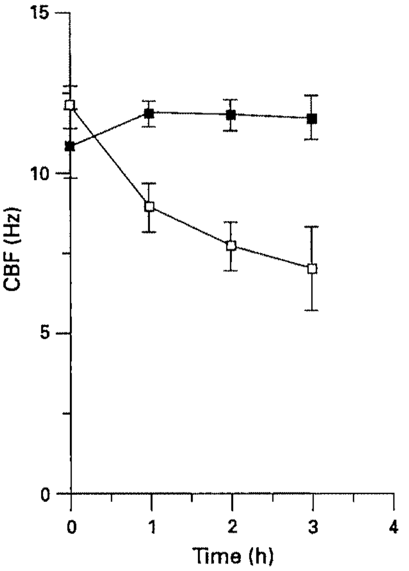

Figure 2 Mean (SEM) nasal cilia beat frequency (CBF) after exposure to 3 MAC of halothane (□) or air (■) for 3 h.

delivery bottle samples and 4.3% (95% CI 3.2 to 5.4) for the samples downstream of the perfusion chamber.

HALOTHANE

There were a total of 349 measurements of cilia beat frequency from the six paired samples exposed to halothane and observed over a 4-h period. Over the 3-h observation period when the cilia were exposed to halothane, mean cilia beat frequency in the group exposed to 3 MAC of halothane in air was 9.3 (SEM 1.3) compared with 11.4 (1.0) in the group exposed to air alone. There was a statistically significant difference between the groups exposed to halothane or air (univariate F test, $F = 9.76$, $P = 0.011$) (fig. 2). The variances at each time for the two treatment groups were not significantly different (Levene's test for equality of variances).

Multiple t tests with Bonferroni correction showed a significant difference between the treatment groups after exposure to halothane for 1, 2 and 3 h (time 0, $P = 1.46$; time 1, $P = 0.028$; time 2, $P = 0.004$; time 3, $P = 0.036$).

ENFLURANE

There were a total of 438 measurements of cilia beat frequency from the six paired samples exposed to enflurane and observed over a 4-h period. Over the 3-h observation period when the cilia were exposed to enflurane, mean cilia beat frequency in the group exposed to 3 MAC of enflurane in air was 10.9 (1.3) compared with 11.6 (1.2) in the group exposed to air alone. The univariate F test was not significant ($F = 2.3$, $P = 0.10$); however, polynomial contrasts were significant for the second polynomial ($F = 6.2$, $P = 0.03$). Thus there was a statistically significant difference between the group exposed to enflurane and the group exposed to air (fig. 3).

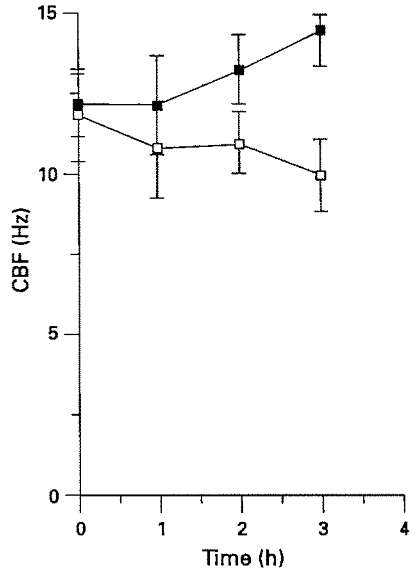

Figure 3 Mean (SEM) nasal cilia beat frequency (CBF) after exposure to 3 MAC of enflurane (□) or air (■) for 3 h.

ISOFLURANE

There were a total of 402 measurements of cilia beat frequency from the six paired samples exposed to isoflurane and observed over a 4-h period. Over the 3-h observation period when the cilia were exposed to isoflurane, mean cilia beat frequency in the group exposed to 3 MAC of isoflurane in air was 10.8 (1.1) compared with 11.6 (1.2) in the group exposed to air alone. The univariate F test was not significant ($F = 3.96$, $P = 0.075$); however, polynomials were significant for the second polynomial ($F = 4.58$, $P = 0.01$). Thus there was a statistically significant difference between the group exposed to isoflurane and the group exposed to air (fig. 4).

Discussion

In this *in vitro* study, we found that 3 MAC of halothane, enflurane and isoflurane significantly reduced cilia beat frequency of human nasal epithelium over a 4-h observation period. There was an unexpected increase in cilia beat frequency in the control group paired with samples exposed to enflurane. The increase in cilia beat frequency in the control group may represent movements of exfoliated collections of cells that became more apparent as the perfusate separated the tissue into smaller segments over time. In our experimental design we controlled for all external factors known to affect cilia beat frequency (temperature, flow rate,

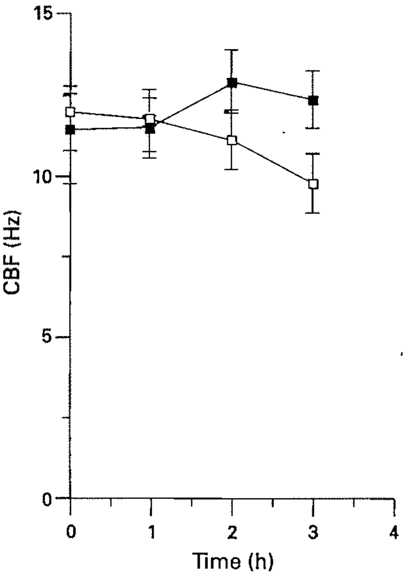

Figure 4 Mean (SEM) nasal cilia beat frequency (CBF) after exposure to 3 MAC of isoflurane (□) or air (■) for 3 h.

pH and osmolality), and when assessing the chamber we found cilia beat frequency to remain stable for many hours [10]. By conducting controlled and blinded experiments we would anticipate that the increase in cilia beat frequency in the control group may have similarly occurred in the paired chamber countered by the depressant effects on cilia beat frequency of the volatile agent.

In this study we used a supraclinical concentration of each volatile agent so as to determine the presence of any effects. This restriction to one concentration makes it impossible to quantitatively compare the agents.

The depressant effects of anaesthetic agents on respiratory mucus clearance are well established [6–8]; however, there has been limited study of the effects of anaesthetics on ciliary function, information relevant to understanding the mechanisms of the depression of mucus transport. The ciliodepressant effects of anaesthetic agents were recognized by Nunn and colleagues 20 yr ago, investigating changes in the swimming velocity of the protozoan, *Tetrahymena pyriformis*, exposed to anaesthetic agents [13]. Manawadu, Mostow and LaForce [14] investigated the effects of halothane on ferret tracheal cilia, but only in a semiquantitative way, by noting the presence or absence of ciliary activity at different sites. Lee and Park demonstrated suppression of cilia beat frequency of rabbit tracheal specimens with halothane and enflurane [15]. They found a 20–25 % reduction in cilia beat frequency with 3 MAC of halothane and enflurane measured after 10 min exposure. This is comparable with the 10 % reduction with enflurane and 25 % reduction with halothane at the earliest time we measured, after exposure for 1 h.

The limited investigations of inhalation anaesthetic agents on cilia beat frequency have been restricted to non-human tissue. Although ciliary structure is similar in different species, ciliary function and in particular mechanisms of control are not uniform. The use of human, rather than non-human, tissue for studying the effects of pharmacological agents in clinical use is therefore preferable. Previous work from our laboratory using a different methodology investigated the effects of halothane on human ciliated tissue [9]. In this study with 1.8 % halothane, there was depression of cilia beat frequency of 25 % after 1 h and 20 % after 2 h exposure and with 5.7 % halothane, reductions of 20 % and 40 % after 1 and 2 h exposure, respectively. These are comparable with our findings of depression of 25 % at 1 h and 40 % after 2 h of exposure to 2.25 % halothane.

The concentration of halothane (measured by gas chromatographic analysis) varied because of loss of some of the agent during sampling as a result of its volatility. The concentration of the volatile agent in the delivery bottle was smaller than downstream of the perfusion chamber, because of the greater difficulties in achieving an airtight seal when sampling from the bottle. The difference in the concentration of halothane in the delivery bottle and downstream of the perfusion chamber was not statistically significant. The derived delivered concentration of halothane downstream of the perfusion chamber with the vaporizer set to 4 % was 4.3 % (95 % CI 3.2 to 5.4) and suggests that this system delivered volatile agents to the ciliated tissue in the sample chamber without significant loss. In an early pilot study, we noted loss of the volatile agent when using plastic connecting tubing and therefore replaced this with metallic tubing.

The ciliated epithelium of the nose sampled in this study has been shown previously to have the same beat frequency as cilia located distally in the bronchial tree [16] and the similarity of our results with those of Lee and Park using rabbit trachea suggests that nasal cells are representative of cilia from more distal parts of the respiratory tract [15]. We have validated our method of sample collection and shown that beat frequency from awake volunteers is the same as that after a sleep dose of propofol [10].

The transmitted light technique for determination of cilia beat frequency first described by Dalmann and Rylander in 1962 is the most widely used method for measurement of cilia beat frequency that is reproducible, convenient to use and requires minimal subjective assessment [17]. We refined Teichtahl's modification [12] by collecting the signals produced by beating cilia over a 15-s period and dividing this into three sequential 5-s intervals for analysis. We computed the peak frequency of one power spectrum obtained by calculating the mean of the power spectra for each epoch. A mean of the dominant frequency of each of the three 5-s epochs was then computed. Although shortening the capture time reduced the resolution of measurement to 0.2 Hz, this was not a limiting factor within the experimental conditions used and it increased the confidence interval of the calculated mean beat frequency.

Postoperative chest infections are a common and serious form of postoperative morbidity and mortality, and a recent study indicated an incidence of 21.5 % after upper abdominal procedures [1]. These infections are associated with smoking [1], vertical surgical incisions [1–4] and prolonged surgery [4].

There is no satisfactory evidence to associate different anaesthetic techniques with the incidence of chest infections. One of the important defences to respiratory infection is mucociliary clearance and this is known to be impaired by some anaesthetic agents [6]; however, the mechanisms involved have not been elucidated. Mucociliary clearance depends on the volume and physical properties of the mucus and the co-ordination and beating frequency of the cilia. It appears that anaesthetic agents may not alter the amount of mucus or its rheological properties [18] and thus it is likely that they alter ciliary function.

We found a 10–25% reduction in cilia beat frequency with these supraclinical concentrations of anaesthetics after 1 h of exposure, yet other workers have demonstrated 80% reduction in the mucus transport rate with similar concentrations of anaesthetic agents [6]. This raises questions about the importance of ciliary beat frequency in determining mucus transport rate.

Forty years ago, Hill investigated the movement of carborundum particles across frog oesophagus and rat trachea [19]. She described a hyperbolic relationship between mucus transport rate and particle velocity such that there were disproportionately larger decreases in mucus transport rates at lower particle velocities. It was hypothesized that this relationship arose because the transfer of power from the beating cilia to the mucus was most effective within a narrow range of ciliary beat frequencies.

Puchelle and Zahm studied the relationship between the transport rate of sputum from bronchitic patients across mucus-depleted frog palate and the rheological properties of sputum [20]. Not surprisingly, the rheological properties of increased viscosity, increased elasticity and reduced spinnability were associated with reduced transport rates; however, the most important determinant of mucus transport rate found by step-by-step multiple regression was ciliary beat frequency.

The exact relationship between cilia beat frequency and the rate of mucus transport is complicated because of the interplay of multiple factors. In a study of 20 patients, Katz and colleagues could not find a direct relationship between cilia beat frequency of human nasal mucosa and tracheal clearance rates using a radioisotope technique. However, in this study the range of mucus transport rates and cilia beat frequencies in the patients studied was small, limiting the chances of finding any relationship if it should exist [21]. Duchateau and co-workers investigated the relationship between nasal cilia beat frequency measured photometrically from biopsies *in vitro* with nasal mucociliary clearance of dye and saccharine *in vivo* in 31 healthy volunteers [22]. The range of mucus transport rates was twice that of Katz's study and a good correlation was found between the logarithm of mucus clearance rate and cilia beat frequency. Hee and Guillerm similarly described a non-linear relationship between cilia beat frequency and mucus transport rates in sheep [23]. These studies suggest that cilia beat frequency may have an important role in determining the transport rate of mucus and that modest reductions in cilia beat frequency may be associated with large reductions in mucus transport rates.

In a separate study [10] we did not find any effect on cilia beat frequency measured 1 h after *in vivo* bolus administration of an induction dose of propofol. This raises the possibility of a difference between this drug and the inhalation agents on respiratory cilia; however, studies of the effects of propofol on cilia beat frequency *in vitro* with on line measurements are required to compare this drug with inhalation agents.

Effect of phosphodiesterase inhibitors on human arteries *in vitro*

M. B. VROOM, M. PFAFFENDORF, H. B. VAN WEZEL AND P. A. VAN ZWIETEN

Summary

In the present study, we investigated if the relaxant effects of phosphodiesterase (PDE) III inhibitors on human vessels could be inhibited by a nitric oxide synthase blocker, L-NAME, or by a blocker of ATP-sensitive potassium channels (K_{ATP}), glibenclamide. The experiments were performed using an isometric myograph in isolated human s.c. small arteries obtained from healthy donors. After a priming procedure consisting of exposure to high potassium (120 mmol litre^{-1}) solutions, phenylephrine 10 μmol litre^{-1} and an equilibrium period of 30 min, the preparations were contracted with a thromboxane A_2 mimetic agent, U46619 1 μmol litre^{-1}. Subsequently, cumulative concentration–response curves were constructed for the selective PDE III inhibitors amrinone, milrinone and enoximone, and for theophylline and dipyridamole, with and without the addition of L-NAME 100 μmol litre^{-1} or glibenclamide 1 μmol litre^{-1}. Addition of L-NAME to the organ bath resulted in significantly higher pEC_{50} values (−log of the concentration required for 50% relaxation) for milrinone compared with the control: 2.77 (SEM 0.24) mol litre^{-1} ($n = 5$) *vs* 3.49 (0.17) mol litre^{-1} ($n = 7$) ($P < 0.05$). There was no significant difference between any other group. From our data we conclude that the relaxant properties of amrinone, enoximone, theophylline and dipyridamole are not dependent on nitric oxide release or on interaction with K_{ATP} channels. However, the effect of milrinone may be partly endothelium-dependent in human vessels *in vitro*. (*Br. J. Anaesth.* 1996; **76**: 122–129)

Key words

Pharmacology, phosphodiesterase inhibitors. Pharmacology, nitric oxide. Pharmacology, glibenclamide. Arteries, relaxation.

Since the discovery of cyclic nucleotide phosphodiesterase (PDE) activity 30 yr ago, there have been major advances in knowledge on this group of enzymes [1]. Five families have been described, each composed of several isoforms with different patterns of tissue distribution, including cardiac muscle, vascular smooth muscle and platelets [2, 3]. Subsequently, selective isoenzyme inhibitors have been developed [4]. Theoretically, these agents may prove useful in a variety of clinical disorders, including heart failure, asthma, depression or dementia, or arterial thrombosis. None the less, their current use in clinical practice is still limited [5].

Over the past decade, interest has focused on the selective inhibitors of the cardiac PDE peak III isoenzyme for the treatment of congestive heart failure, but the effects of chronic oral administration of these inotropic agents in this condition have been disappointing [6–8]. However, they continue to be used in the treatment of acute heart failure [9, 10]. One of the disadvantages of the currently available PDE III inhibitors, such as amrinone, milrinone and enoximone, is marked vasodilator activity at higher doses, with concomitant reductions in arterial pressure.

The precise mechanism of this vasodilator activity remains to be elucidated. There is little doubt that selective inhibition of a low K_m cAMP PDE, documented in both human arteries and arteries of different animal species, plays a major role [11–15]. In addition, several PDE inhibitors have been shown to produce endothelium-dependent vasodilatation in animal studies [16–18]. Recently, there has been mounting interest in the role of the ATP-dependent potassium (K_{ATP}) channels in cardiovascular tissue. Opening of these K_{ATP} channels may result not only in vasodilatation, but also in marked cardioprotective anti-ischaemic effects [19, 20].

In the present study, we investigated if the vasodilator effects of the PDE III inhibitors amrinone and milrinone, both bipyridines, the imidazolone derivative, enoximone, and the non-specific PDE inhibitors, theophylline and dipyridamole, could be modulated by a nitric oxide synthase blocker, N^G-nitro-L-arginine methyl ester hydrochloride (L-NAME) or by the K_{ATP} channel blocker, glibenclamide. The experiments were performed in isolated human s.c. small arteries, obtained from healthy donors.

Materials and methods

VESSEL DONORS

S.c. arteries were obtained from 11 healthy white female patients (aged 18–49 yr) undergoing reconstructive breast surgery. The study was approved by the hospital's medical Ethics Committee and all patients gave informed consent. The patients were free from cardiovascular disorders and were not

receiving any chronic drug treatments, except for oral contraceptive agents. Surgery was performed under general anaesthesia with volatile anaesthetics, supplemented with fentanyl and vecuronium.

PREPARATION AND MOUNTING OF THE VESSELS

Small arteries were dissected atraumatically, immediately after removal of a skin segment with s.c. fat from the caudal segment of the patient's breast. After dissection, a 40-µm diameter stainless steel wire was inserted into the lumen. The length of the vessels was determined using an OSM-4 10×/13 ocular lens (Olympus, Japan). Subsequently, the vessels (estimated length of 1–2 mm) were placed in an organ preservation solution (University of Wisconsin (UW)) [21] and stored at 4 °C for a maximum of 7 days. Before the experiment, the preparations were transferred to the chamber of an isometric myograph [22]. The wire was fixed at both ends to microscrews and a second wire was inserted, which was subsequently connected to a force transducer (Kistler Morse, DSG 6, Redmond, WA, USA). This enabled continuous measurement of the isometric wall tension of the vessel. Reproducible measurements could be obtained within at least 7 h.

The preparations were suspended in Tyrode's solution for 10 min at 37 °C. Throughout the experiment, the buffer solution was oxygenated with carbogen (95% oxygen, 5% carbon dioxide) to achieve a pH of 7.4. Subsequently, the ratio between passive wall tension and internal circumference was determined by a normalization procedure, as described by Mulvany and Halpern [23]. The internal circumference was adjusted to a value that equals 90% of the circumference generated by a transmural pressure of 100 mm Hg (13.3 kPa). This value was then divided by π to obtain the normalized lumen diameter. Mechanical responses were expressed as active tension, δT (N m^{-1}), that is the developed active force divided by twice the vessel segment length.

At the beginning of each experiment, the preparations were contracted three times for 5 min with high potassium Tyrode's solution (K^+ 120 mmol litre^{-1}, see below) and once with phenylephrine 10 µmol litre^{-1}, an α_1 adrenoceptor agonist, at intervals of 15 min. Between these episodes the chambers were flushed at least three times with Tyrode's solution. This episode was followed by an equilibrium period of 30 min for the L-NAME and control groups and 60 min for the glibenclamide group. L-NAME 100 µmol litre^{-1} or glibenclamide 1 µmol litre^{-1} was added at the beginning of this period and remained present in the bath thereafter. An equilibrium period of 60 min was chosen for glibenclamide as this drug has a slow onset of action. Subsequently, U46619, a thromboxane A_2 mimetic agent, was administered to all preparations at a concentration of 1 µmol litre^{-1}. After stabilization of the contraction, a cumulative concentration–response curve, using concentrations of 0.1 µmol litre^{-1} to 1 mmol litre^{-1}, was constructed for amrinone, milrinone, enoximinone, theophylline and dipyridamole.

Our experimental model included two separate force transducers connected to one single organ bath, which enabled simultaneous evaluation of the contractile responses of two vessels to one drug combination. Therefore, the experiments described were performed in duplicate if sufficient vessels could be harvested from the patient's breast. The data of these duplicate experiments were averaged and listed in the results section for each individual patient.

To evaluate the effects of the preservation technique on endothelial function, the response of contracted arteries to methacholine 10^{-5} mol litre^{-1} was determined immediately after dissection of the blood vessel and after preservation in UW fluid. These vessels were not used in any other experiment.

SOLUTIONS AND DRUGS USED

In all experiments, Tyrode's solution of the following composition was used (mmol litre^{-1}): NaCl 136; $NaHCO_3$ 11.9; NaH_2PO_4 0.42; KCl 2.5; $CaCl_2$ 1.8; $MgCl_2$ 0.5; and glucose 5.5. In the high potassium Tyrode's solution, NaCl 117.5 mmol litre^{-1} was replaced by KCl, resulting in a total potassium concentration of 120 mmol litre^{-1}. These solutions were prepared just before each experiment. Aliquots of 20 ml were kept at 37 °C and bubbled with carbogen before they were introduced into the bath.

Amrinone and milrinone (donated by Sanofi Winthrop, Dev. Centre, Fawdon, UK) and enoximone (donated by Marion Merrell Dow Inc., Cincinatti, OH, USA) were dissolved to a concentration of 10^{-1} mol litre^{-1}. Milrinone was dissolved in distilled H_2O, amrinone and enoximone were dissolved in 99% dimethylsulphoxide (DMSO). Subsequently, these agents were diluted to 10^{-2}–10^{-5} mol litre^{-1} in distilled water (amrinone and milrinone) or 66.7% DMSO (enoximone).

Theophylline and dipyridamole (Sigma Chemical Co., USA) were dissolved in distilled water and 66.7% DMSO, respectively, and subsequently diluted to 10^{-2}–10^{-5} mol litre^{-1} in distilled water. The final concentrations ($<1\%$) of DMSO in the bathing medium had no significant effect on vascular smooth muscle contraction and relaxation. (See fig. 1 for the chemical structures of the various compounds studied.)

Nitro-L-arginine methyl ester hydrochloride (L-NAME) (Sigma), U46619 (9,11-dideoxy-11α,9α-epoxy methanoprostaglandin F2α) (Sigma) and L-phenylephrine hydrochloride (Sigma) were dissolved in distilled water. Glibenclamide (Hoechst) was dissolved in 66.7% DMSO.

DATA ANALYSIS

A log concentration–response curve was fitted to the data of individual experiments using GraphPad software (GraphPad, Institute for Scientific Information, San Diego, CA, USA). This computer program allows calculation of the EC_{50} by non-linear regression analysis, which is the concentration of the compound required to achieve the half maximal relaxant effect, based on the equation: E =

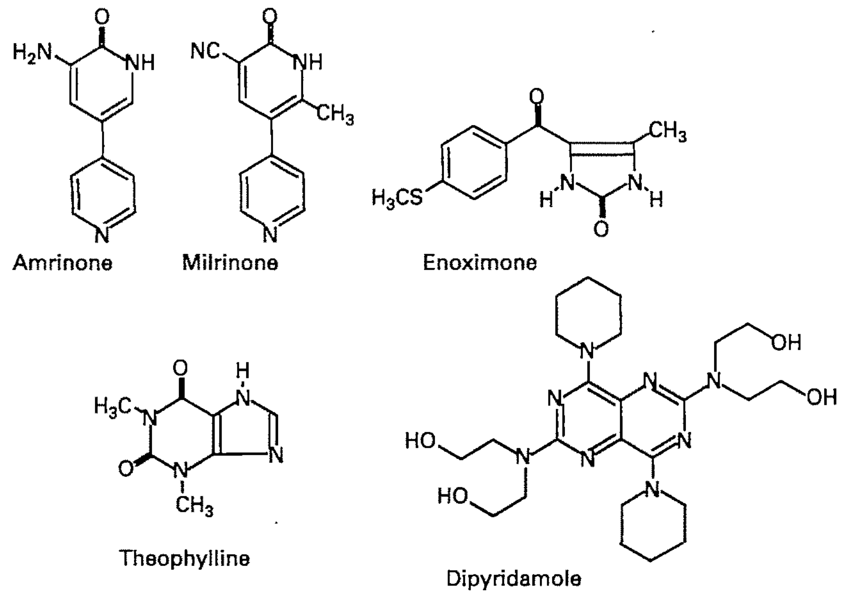

Figure 1 Chemical structures of the various compounds studied.

Emax × $A^P/(A^P + EC_{50}{}^P)$, where E = the response obtained with a given concentration A; the exponent P describes the slope of the relationship (Hill coefficient); and Emax = the maximally obtainable effect.

All data are presented as mean (SEM). Differences between means were compared using a two-tailed Student's t test for unpaired data or analysis of variance where appropriate (Graphpad Instat). $P < 0.05$ was considered significant.

Results

The resistance arteries dissected from the mammary tissues and used to evaluate the effects of the PDE III inhibitors ($n = 116$) had an average diameter of 415 (20) µm and a length of 1.8 (0.03) mm. There were no significant differences in main vessel characteristics between the groups (table 1).

All arteries showed spontaneous rhythmic activity under the experimental conditions. The preparations remained stable and fully responsive to methacholine for at least 1 week after preparation when stored in the UW solution. Maximal relaxation to methacholine 10^{-5} mol litre^{-1} was 97.5 (1.5)% ($n = 4$) on day 0 *vs* 97.3 (1.8)% ($n = 4$) on day 7 (ns). Preservation UW fluid had no influence on the contractile response to U46619 1 µmol litre^{-1}, as linear regression analysis revealed no time-dependent change (correlation coefficient $r = 0.159$, slope not significantly different from zero) (fig. 2). In addition, the contractile responses to phenylephrine remained stable with time: 3.92 (0.32) N m^{-1} ($n = 22$) on day 0 *vs* 5.05 (1.62) ($n = 4$) (ns) on day 7.

All PDE inhibitors induced concentration-dependent vasodilatation in the isolated arteries. Dipyridamole was the most potent vasodilator in our study (pEC_{50} 4.67 (0.22) mol litre^{-1}) and theophylline the least active (pEC_{50} 2.72 (0.07) mol litre^{-1}). The pEC_{50} values for amrinone, milrinone and enoximone were similar in the control groups: 3.28 (0.01), 3.49 (0.17) and 3.29 (0.08) mol litre^{-1}, respectively.

Compared with potassium and phenylephrine, U46619 proved to be the most potent vasoconstrictor

in all experiments. The contractile response to U46619 was not influenced by the administration of L-NAME or glibenclamide. The basal values of the U46619-induced response were comparable in all preparations (table 2). Of the 85 experiments described in table 2, 31 experiments were performed in duplicate, accounting for the total of 116 experiments. Both the contractile response to U46619 and the vasodilator effects of amrinone, milrinone, enoximone, theophylline and dipyridamole were completely reversible on washout.

The contractile responses to the fourth potassium administration and to phenylephrine are shown in table 3. Amrinone was administered in cumulative concentrations of 10^{-8} to 10^{-3} mol $litre^{-1}$. At the highest concentration, amrinone caused relaxation of U46619-induced contraction by 72.4% of the initial value. Milrinone and enoximone were also administered in a concentration range of 10^{-8}–10^{-3} mol $litre^{-1}$. The maximal relaxant effects were 71.4% and 82.2%, respectively. Theophylline proved less potent and effective, as higher doses were required (3.10^{-3} mol $litre^{-1}$) and a lower degree of maximal relaxation (57.8%) was achieved. Dipyridamole

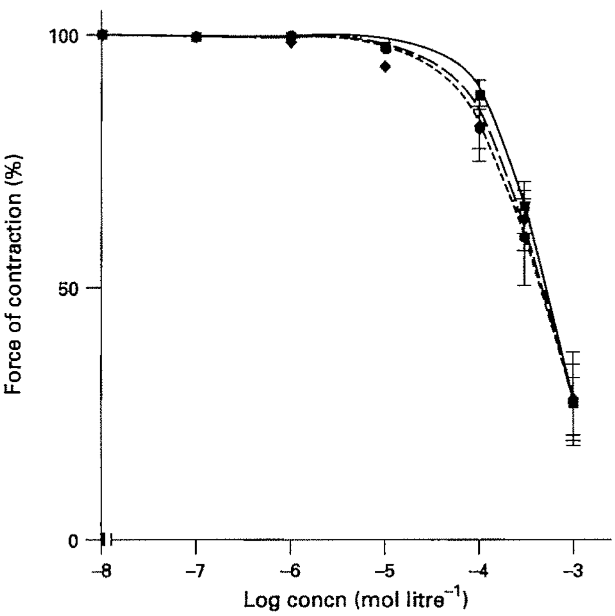

Figure 3 Log concentration-response curve for amrinone in the absence (control (n = 6) (■)) or presence of L-NAME (n = 5) (◆) or glibenclamide (n = 6) ●).

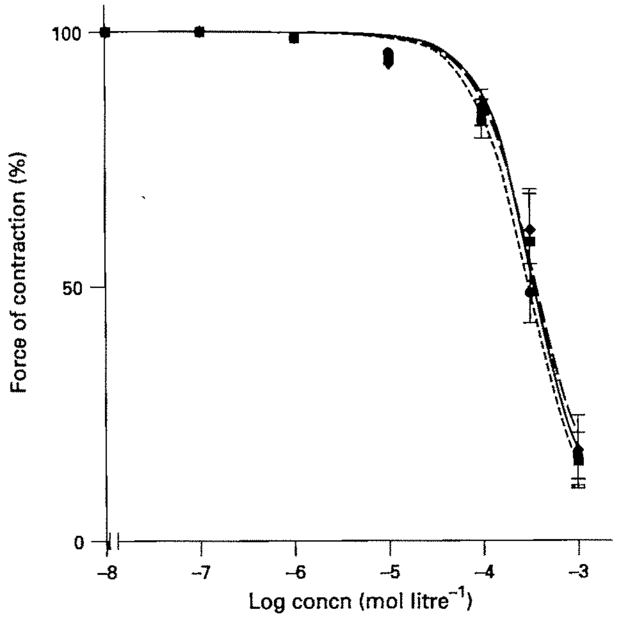

Figure 4 Log concentration-response curve for enoximone in the absence (control ($n = 6$) (■)) or presence of L-NAME ($n = 5$) (◆) or glibenclamide ($n = 6$) (●).

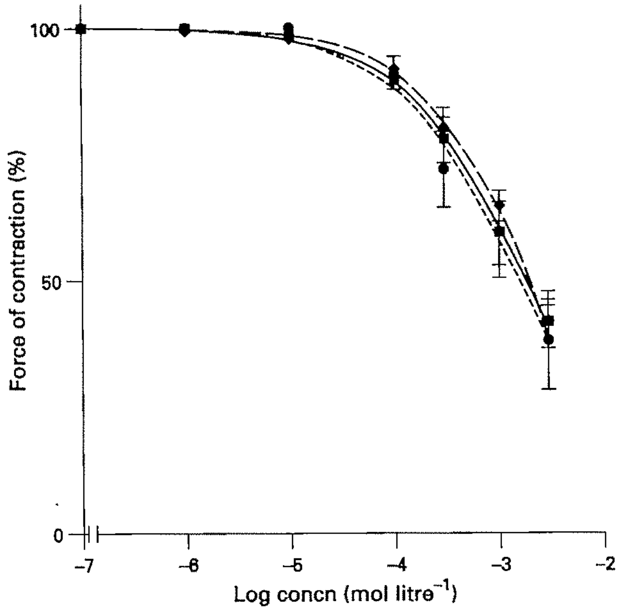

Figure 5 Log concentration-response curve for theophylline in the absence (control ($n = 5$) (■)) or presence of L-NAME ($n = 5$) (◆) or glibenclamide ($n = 8$) (●).

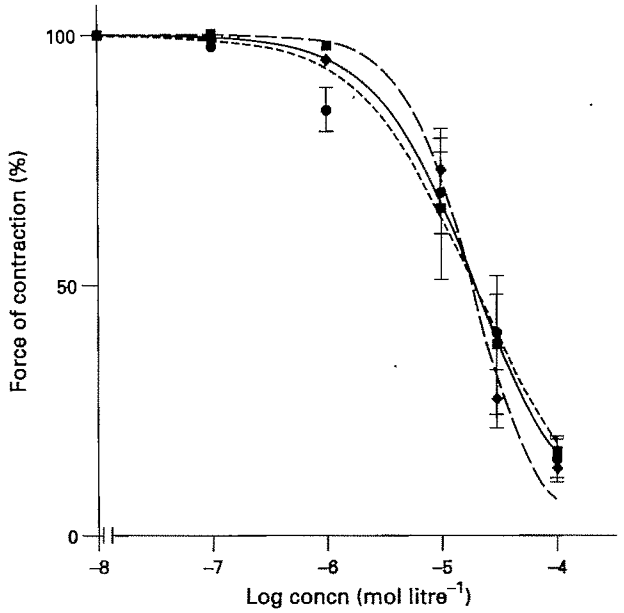

Figure 6 Log concentration-response curve for dipyridamole in the absence (control ($n = 5$) (■)) or presence of L-NAME ($n = 5$) (◆) or glibenclamide ($n = 5$) (●).

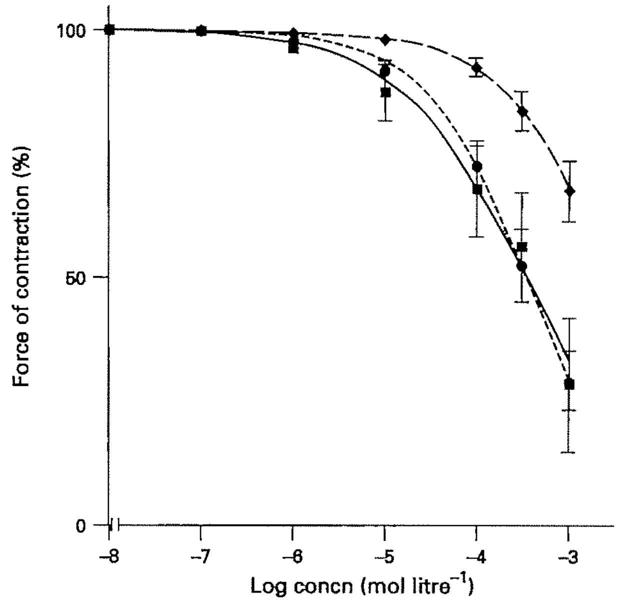

Figure 7 Log concentration-response curve for milrinone in the absence (control ($n = 7$) (■)) or presence of L-NAME ($n = 5$) (◆) or glibenclamide ($n = 6$) (●). In the presence of L-NAME, a significant ($P < 0.05$) rightward shift of the relaxation curve was observed.

concentrations ranged from 10^{-8} to 10^{-4} mol litre^{-1}, resulting in 83% maximum relaxation of the basal value.

Neither L-NAME nor glibenclamide influenced the basal value of the contractile response to U46619 when administered simultaneously with the PDE inhibitors. In addition, neither L-NAME nor glibenclamide influenced the relaxant responses to amrinone, enoximone, theophylline or dipyridamole (table 4 and figs 3–6). However, in the presence of L-NAME a significant ($P < 0.05$) rightward shift was observed in the relaxation curve of milrinone. Accordingly, the pEC$_{50}$ values of milrinone were also influenced by L-NAME: 2.77 (0.24) mol litre^{-1} with L-NAME compared with 3.49 (0.17) mol litre^{-1} without L-NAME ($P < 0.05$) (fig. 7).

Discussion

Using animal models, several investigators have demonstrated that the PDE III inhibitors amrinone, milrinone and enoximone induce vasodilatation as a result of inhibition of cGMP-inhibited (cGI) PDE, thus leading to increased intracellular levels of cAMP [11–14]. The effects of theophylline and dipyridamole on vascular smooth muscle are more complex. The mode of action of theophylline involves both non-specific phosphodiesterase inhibition and adenosine receptor antagonism [24]. In addition, unknown cellular mechanisms appear to play an additional role [25]. Dipyridamole is not only a PDE inhibitor, but also modulates adenosine metabolism, as it inhibits the cellular uptake of adenosine [26, 27].

In the present study, all agents caused concentration-dependent vasodilatation. The concentrations required were rather high compared with the results reported in the literature. However, these data may not be comparable with our results as various types of tissues were used in these studies and were obtained from different species. The use of human vessel preparations provides an obvious advantage when studying the action of agents with an influence on PDE activity, as the distribution of PDE isoenzymes is known to differ considerably between species [28]. Only Lindgren and colleagues used human vessels in their studies, but these tissues were obtained either post mortem or from patients undergoing laparotomy for various abdominal disorders, and not from healthy patients as in our study [11, 29]. Interestingly, these authors showed the importance of the mode of produced contraction on both the magnitude of the relaxant effect and the potency of PDE inhibitors on human vessels *in vitro*. Contractions of isolated arteries induced by high potassium concentrations (K^+ 127 mmol $litre^{-1}$) were more difficult to relax by PDE III inhibitors compared with lower K^+ concentrations (30 mmol $litre^{-1}$) or noradrenaline-induced contractions. Similarly, Harris and colleagues demonstrated a difference in efficacy of PDE III inhibitors in voltage-dependent (K^+ 80 mmol $litre^{-1}$) as opposed to receptor-mediated (U46619) vasoconstriction [30]. The response to the PDE inhibitors in the present study may, therefore, be related partially to the method by which vasoconstriction was induced. Other important factors which may influence the efficacy of PDE inhibitors are the characteristics of the vascular beds from which the human vessels are taken. Marked variations in vascular responsiveness of isolated human coronary, renal and lung arteries have been demonstrated by Lindgren and Andersson [29]. In potassium (30 mmol $litre^{-1}$) contracted lung arteries, cGI-PDE inhibitors (including milrinone 3×10^{-5} mol $litre^{-1}$) were incapable of producing 50% relaxation. In contrast, the agents investigated were significantly more potent and effective in renal and coronary arteries (pEC_{50} for milrinone: 3.2×10^{-6} and 1.7×10^{-6} mol $litre^{-1}$, respectively). This reduced efficacy in both lung arteries in the aforementioned investigation and mammary arteries in our study may indicate low cGI-PDE activities in these particular tissues.

Although not all vessels were used immediately after dissection, but stored in UW organ preservation fluid, there were no differences between the vessel characteristics, including maximal force development and function of endothelium (response to methacholine), between vessels of several minutes to several days old. Therefore, it is unlikely that this preservation technique was responsible for these findings. Thus far there are no reports in the literature that document the preservation of isolated vessel preparations in UW solution. Successful preservation in UW fluid for 72 h, however, has been demonstrated for entire organs taken from animals [31, 32].

In our study, only the vasodilator effects of milrinone were partially endothelium-dependent. The addition of L-NAME 100 μmol $litre^{-1}$ resulted in a significant ($P < 0.05$) increase in the pEC_{50} value of milrinone compared with controls: 2.77 (0.24) *vs* 3.49 (0.17) mol $litre^{-1}$, respectively. So far we cannot explain why the vasodilator profile of milrinone was distinctly different from that of its structurally related analogue, amrinone. Harris and colleagues also described differential relaxant effects of milrinone and amrinone in canine arteries [30]. In their study milrinone proved a more potent vasodilator against receptor-mediated (U46619) as opposed to K^+-induced depolarizations, whereas amrinone appeared equipotent in these conditions. The reason for these different effects could not be elucidated.

Limited data are available in the literature on the interaction between the currently used PDE inhibitors and endothelium. Amrinone was reported to cause vasodilatation by both endothelium-dependent and -independent mechanisms in small pulmonary arteries of rabbits [16]. The vasodilator effects of enoximone in isolated porcine pulmonary arteries were endothelium-independent and unchanged by the addition of L-NAME 10^{-4} mol $litre^{-1}$ [33]. Finally, Kauffman and colleagues demonstrated that the vasodilator effects of milrinone in concentrations ranging from 10^{-7} to 10^{-5} mol $litre^{-1}$ occurred predominantly independent of the presence of an intact endothelium in aortic strips from rats [14]. In addition, these authors demonstrated that a high concentration of milrinone (10^{-4} mol $litre^{-1}$) resulted in increased concentrations of the second messenger cGMP next to enhanced levels of the intracellular mediator cAMP. Furthermore, in the presence of methylene blue, the dose–response curve for milrinone was shifted to the right. Methylene blue acts as an inhibitor of soluble guanyl cyclase and also nitric oxide synthase [34]. Clearly the mechanism by which PDE inhibitors induce vasodilatation is complex, as recent evidence has been obtained demonstrating that cross-interactions between cAMP and cGMP occur at different levels [35, 36].

At high concentrations milrinone acts on PDE IV and PDE V, next to PDE III inhibition [36], PDE IV hydrolyses cAMP, whereas PDE V acts as a specific cGMP hydrolyser. It has been demonstrated that vasodilatation induced by selective PDE IV inhibitors were abolished by both L-NAME and methylene blue, indicating that the effect of PDE IV inhibitors is dependent on nitric oxide production and subsequent activation of soluble guanylate cyclase [36]. Thus, the aforementioned results combined with our data may indicate that milrinone acts as a PDE III inhibitor, independent of endothelial function, at low concentrations, whereas at higher concentrations ($> 10^{-5}$ mol $litre^{-1}$) the inhibitory activity of milrinone on PDE IV, which can be partially abolished by L-NAME becomes more prominent.

The interaction of glibenclamide with milrinone was reported by Fujimoto [37]. In his experiments, inhibition of milrinone-induced vasodilatation by glibenclamide in vascular preparations of rats and guineapigs, was demonstrable only at glibenclamide concentrations as high as 10–30 μmol litre^{-1} [37]. However, at these high concentrations glibenclamide may not act as a specific K_{ATP} channel blocker [38]. In the present investigation glibenclamide 1 μmol litre^{-1} did not influence the vasodilator effect of any of the PDE inhibitors studied, indicating that K_{ATP} channels are not involved in the process of vasodilatation caused by these agents.

In conclusion, L-NAME sensitive nitric oxide release may contribute to the vasodilator properties of milrinone, but not to those of any of the other PDE inhibitors studied. Vasodilatation caused by PDE inhibitors does not appear to involve K_{ATP} channels.

Effect of pneumoperitoneum and Trendelenburg position on gastro–oesophageal reflux and lower oesophageal sphincter pressure

J. P. TOURNADRE, D. CHASSARD, K. R. BERRADA AND P. BOULETREAU

Summary

We have measured the effect of pneumoperitoneum and the Trendelenburg position on lower oesophageal sphincter (LOSP) and barrier pressures (BrP) in 11 anaesthetized pigs while measuring the incidence of gastro–oesophageal reflux with a pH electrode. Propofol in combination with sufentanil had no effect on LOSP or BrP. Adoption of the Trendelenburg position with a pneumoperitoneum of 15 mm Hg resulted in a significant increase in LOSP ($P < 0.002$) and BrP ($P < 0.001$). However, in two of 11 pigs who had the lowest LOSP before induction, there was regurgitation. (*Br. J. Anaesth.* 1996; **76**: 130–132)

Key words

Complications, regurgitation. Gastrointestinal tract, lower oesophageal sphincter. Position, Trendelenburg. Surgery, laparoscopy. Pig.

Factors which increase lower oesophageal sphincter pressure (LOSP) usually also increase oesophageal barrier pressure (BrP = LOSP − gastric pressure). To date, only one study found that increased intra-abdominal pressure and Trendelenburg position resulted in an increase in LOSP and it was concluded that laparoscopy did not necessarily increase the likelihood of regurgitation [1]. However, reflux was not measured and oesophageal pressures were not recorded before induction of anaesthesia. We have therefore studied in pigs the effects of anaesthesia, pneumoperitoneum and Trendelenburg position on LOSP and gastro-oesophageal reflux.

Materials and methods

After obtaining approval from our Institutional Animal Care Committee, we studied 11 pigs (weight 22–25 kg). Ketamine 8 mg kg^{-1} i.m. was given as premedication after a 12-h fast. Anaesthesia was induced with propofol 5 mg kg^{-1}, sufentanil 3 μg kg^{-1} and pancuronium 0.1 mg kg^{-1} i.v. The trachea was intubated with a 6-mm cuffed tube and the lungs ventilated artificially using a MMS 107 ventilator (MMS, Pau, France) with a tidal volume of 15 ml kg^{-1} at a ventilatory frequency of 12–15 b.p.m. (normocapnia at baseline using an Engström Eliza capnograph). Anaesthesia was maintained with a continuous infusion of propofol 10 mg kg^{-1} h^{-1}. Carbon dioxide was insufflated through a Veress needle inserted through a 2-cm abdominal midline incision. Intra-abdominal pressure was maintained at 15 mm Hg (Wolf, Knittlingen, Germany).

The technique of oesophageal manometry has been described previously [2, 3]. Briefly, LOSP, gastric (GP) and intraperitoneal pressures (IPP) were measured with the pig in the supine position using perfused polyethylene catheters connected to pressure transducers (Bentley Trantec, Irvine, CA, USA). Recordings of LOSP were made at end-expiration by a "pull-through" manoeuvre. Transducers were zeroed at the level of the midchest position. Before each investigation, the system was calibrated in a water column (0–50 cm H_2O) and perfused continuously using a low compliance system (SC 2000 pump, Sky Electronics). Pressures were recorded using a multiple channel recording system (Kontron Medical) before induction (T0), after induction (T1), at an intra-abdominal pressure of 15 mm Hg (T3), at a pressure of 15 mm Hg with 15° of Trendelenburg position (T4) and finally with the pig supine again (T5).

Oesophageal pH was measured continuously using a bipolar glass electrode (Ecosecur pH recorder, Tacussel). The electrode was calibrated before each set of measurements with standardized solutions of buffer at pH 3 and 7. The electrode was advanced until gastric pH was recorded. It was then withdrawn to the gastro–oesophageal junction, recognized by an abrupt increase in pH, and finally positioned 5 cm above the junction. Reflux was defined as an abrupt decrease in oesophageal pH to less than 4 [2, 4].

Statistical significance was determined using a paired Wilcoxon test. $P < 0.05$ was considered statistically significant.

Results

Baseline LOSP and BrP were in the normal range for pigs. LOSP was not affected by anaesthesia and BrP remained above 10 mm Hg (table 1).

The Trendelenburg position, pneumoperitoneum, or both, increased LOSP, while significant increases in BrP and LOSP were noted only after

Table 1 Effect of anaesthesia, pneumoperitoneum and Trendelenburg position on lower oesophageal sphincter pressure (LOSP) and barrier pressure (BrP = LOSP − gastric pressure) in anaesthetized pigs (mean (SD)). IPP = Intraperitoneal pressure. $^{**}P < 0.01$, $^{***}P < 0.001$

	Baseline	After induction	IPP of 15 mm Hg	Trendelenburg + IPP of 15 mm Hg	IPP of 15 mm Hg
LOSP (mm Hg)	19.1 (9.3)	16.4 (7.8)	31.0 (14.5)**	42.6 (19.7)**	31.0 (14.8)**
BrP (mm Hg)	15.2 (8.8)	12.5 (8.5)	13.7 (12.8)	20.9 (17.8)***	13.7 (12.4)

the combination of pneumoperitoneum and Trendelenburg position. During the Trendelenburg position, the increase in LOSP was greater than the change in IPP (LOSP: 42.6 − 16.4 = 26.2 mm Hg *vs* IPP = 15 mm Hg) (table 1). Two of 11 pigs exhibited prolonged gastro–oesophageal reflux during pneumoperitoneum: both had a BrP lower than 0 mm Hg (0 and −2 mm Hg) at the time of reflux. Before and after induction, BrP was lower in these two pigs with reflux than in pigs without reflux: 7 (SD 1) compared with 17.1 (8.7) mm Hg and 5 (1) compared with 14.2 (6.5) mm Hg, respectively.

When the Trendelenburg position was reversed and the pigs placed supine, gastric pressure decreased to values similar to those recorded during pneumoperitoneum.

Discussion

We have demonstrated that lower oesophageal sphincter pressure increases significantly in response to increases in intra-abdominal pressure. However, in some animals, there was gastro–oesophageal reflux.

As in humans, the musculature of the porcine distal oesophagus consists of smooth muscle fibres [5]. Recent studies have shown that the pressure at the LOS is created not only by contraction of these smooth muscles but also by the striated muscle of the crural diaphragm [6]. Previous studies have demonstrated that drugs commonly used during anaesthesia such as atropine [7], benzodiazepines [2], morphine [2], thiopentone [3] and halothane [8] can affect the competency of the lower oesophageal sphincter. In contrast, ketamine has no effect on LOSP [9]. In a clinical study, Roberts and Goodman [10] did not observe any reflux episodes in 63 patients anaesthetized with propofol and fentanyl. In our study, we demonstrated that propofol associated with sufentanil had no effect on LOSP and BrP in pigs.

After adopting the Trendelenburg position, as the increase in LOS pressure was far greater than the change in gastric pressure, BrP increased. Heijke, Smith and Key [11] showed that adoption of the Trendelenburg position alone (15° and 30°) did not change BrP in female patients during balanced anaesthesia, and Lind, Warrian and Wankling [7] found that increasing IPP resulted in an increase in BrP. Jones, Mitchell and Hindocha [1] reported that the combination of Trendelenburg 15° and IPP at 20 mm Hg resulted in an increase in BrP, results similar to our findings. Increasing intra-abdominal or intragastric pressures by straight-leg raising or abdominal compression results in a concomitant increase in LOS pressure in animals as in human volunteers [12]. During anaesthesia, this adaptive response to increases in gastric pressure has been reported to be mediated partially via a cholinergic pathway as atropine reduced LOS tone [6].

During laparoscopy, carbon dioxide insufflation increases IPP and gastric pressure. Some clinical studies have evaluated the incidence of regurgitation during laparoscopy as 2–20% [10, 13], an incidence no greater than that during other surgical procedures [14]. We also found a 20% incidence of reflux (two of 11 pigs). Jones, Mitchell and Hindocha [1] have shown the presence of an adaptive response in LOSP in response to peritoneal insufflation up to 30 cm H_2O. Heijke, Smith and Key [11] reported a small increase in gastric pressure during 30° Trendelenburg position, but BrP was not affected. It was concluded from these manometric studies that laparoscopy does not increase the risk of regurgitation. However, these manometric studies are not conclusive as intraoperative recording of oesophageal pH was not undertaken. In contrast, our results showed that reflux may occur in some animals because the adaptive response was not always present. We noted in two pigs that BrP was lower than 0 mm Hg during episodes of reflux and that these pigs had the lowest LOSP and BrP values throughout the study. Although it is well established that there is a relationship between a decrease in LOSP and reflux [15], it is not possible at this time to define BrP or LOSP values below which reflux will occur. Any decrease in BrP during anaesthesia would be expected to increase the risk of regurgitation and this is particularly true in situations where LOSP is initially low.

From this study we suggest that in an individual patient it is not possible to predict that the adaptive response of the LOS protects against regurgitation during laparoscopy.

REVIEW ARTICLE

Recent developments in the pathophysiology and management of pre-eclampsia

M. C. MUSHAMBI, A. W. HALLIGAN AND K. WILLIAMSON

Fits occurring in pregnant women were recognized and recorded as early as the 4th century BC by Hippocrates [94]. The condition was termed eclampsia—a Greek word which translates literally as 'shine forth'—implying a sudden development. Little was known about eclampsia until 1843, when Lever of Guy's Hospital found that many of the women who had fits also had albumin in their urine [74]. However, it was not until the widespread use of the sphygmomanometer that the condition was known to be associated with raised systemic arterial pressure. Because it was recognized that albuminuria and hypertension could precede the onset of fits, the term pre-eclampsia was coined although this nomenclature is now criticized because only a small proportion of patients with pre-eclampsia subsequently develop eclampsia.

Pre-eclampsia is a multisystem disorder of unknown aetiology and unique to pregnant women after 20 weeks' gestation. In the UK, 18.6 % of maternal deaths are caused by hypertensive diseases [42]. Hypertensive disorders of pregnancy are common, affecting 10.6 % of pregnant women [109]. Pre-eclampsia (i.e. proteinuric hypertension) affects 5.8 % of primigravidas, and 0.4 % of secundagravid women [84]. While premature labour is the leading cause of very low birthweight neonates, the next most common cause is hypertension which accounts for 23 % of all viable very low birthweight singleton infants [2].

Pre-eclampsia is a progressive disease with a very variable mode of presentation and rate of progression. Of all the features of the syndrome, hypertension, pregnancy-induced proteinuria, excessive weight gain and oedema are the classic clinical manifestations. Other features include, thrombocytopenia, hyperuricaemia, abnormal liver function tests, haemoconcentration, hypoalbuminaemia and eclampsia.

Eclampsia is a rare but serious complication of pre-eclampsia; it complicates about 1:2000 deliveries in Europe and the developed countries [45] and from 1:100 to 1:1700 deliveries in developing countries [34]. The higher incidence in countries with poor economies is thought to result from inadequate antenatal care with late presentation of patients to hospital. In the UK, 38 % of convulsions occur before the diagnosis of proteinuric pre-eclampsia is made and 44 % occur in the postpartum period. Teenage patients and mothers with multiple pregnancies have a higher risk of developing fits. Eclampsia which occurs antenatally carries more complications than when the condition develops in the intrapartum or postpartum periods [45]. In the UK, eclampsia contributes to 10 % of maternal deaths [42]. The complications of eclampsia are shown in table 1.

Despite decades of research, the pathogenesis of pre-eclampsia is still not understood fully but it is generally accepted that the underlying pathological changes occur in the placenta and placental bed. Early recognition of the syndrome still presents a challenge to clinicians as there is no specific diagnostic test, and treatment is based on management of symptoms and prevention of complications rather than specific therapy.

Classification

The classification and definition of hypertensive disorders during pregnancy continue to generate controversy. The current recommended classification is that by the International Society for the Study of Hypertension (ISSHP) [38]. This recognizes four categories in pregnancy (table 2). Gestational or pregnancy-induced hypertension is caused by the pregnancy itself whereas chronic hypertension refers to pre-existing elevation in arterial pressure.

Definition and diagnosis

Pre-eclampsia cannot be defined accurately until its cause is known. For many years, the syndrome was considered to comprise hypertension, oedema and proteinuria occurring after 20 weeks' gestation, not because these were the most important features but because, historically they were the first to be

Table 2 Classification of hypertensive diseases in pregnancy [38]

A. Gestational hypertension and/or proteinuria developing during pregnancy after 20 weeks' gestation in a previously normotensive, non-proteinuric woman.
  1. Hypertension without proteinuria
  2. Proteinuria without hypertension
  3. Gestational proteinuric hypertension (pre-eclampsia).

B. Chronic hypertension and chronic renal disease
  1. Chronic hypertension without proteinuria
  2. Chronic renal disease diagnosed before, during or persisting after pregnancy
  3. Chronic hypertension with superimposed pre-eclampsia.

C. Unclassified hypertension and/or proteinuria which is found at the first antenatal visit after 20 weeks' gestation in a woman whose past hypertensive status is unknown.

D. Eclampsia is the occurrence of generalized convulsions during pregnancy, labour or within 7 days of delivery in the absence of epilepsy or another condition predisposing to convulsions.

Table 3 Definition of pre-eclampsia [38]

1.	Gestation	> 20 weeks
2.	Arterial pressure	Diastolic > 110 mm Hg on any one occasion OR Diastolic > 90 mm Hg on 2 or more occasions at least 4 h apart
3.	Proteinuria	> 300 mg in 24 h OR 2 clean-catch mid-stream or catheter specimens of urine collected at least 4 h apart with: (1) 1 g albumin litre^{-1} OR $\geqslant$ 2+ on reagent strip OR (2) 0.3 g albumin litre^{-1} or $\geqslant$ 1+ on reagent strip if urine pH is < 8 or specific gravity is < 1.030
4.	Oedema	Not essential for diagnosis

recognized. Despite the problems of definition, the ISSH has produced a useful pragmatic version which is shown in table 3.

Oedema is not included in this definition because moderate degrees of oedema may be detected in 80% of normotensive pregnant women, most of whom are healthy. Pathological oedema affects 85% of women with proteinuric pre-eclampsia; it appears relatively suddenly and is associated with accelerated weight gain. However, eclampsia without oedema has been recognized for many years as particularly dangerous while more recently, 32% of a series of eclamptic patients were noted to have no oedema [119]. The perinatal mortality in pre-eclampsia without oedema is higher than when the condition exists with oedema.

The difficulties with definition of hypertension in pregnancy are caused partly by problems in measurement of arterial pressure and partly by the controversy in identifying the optimal threshold level for diastolic pressure.

MEASUREMENT OF ARTERIAL PRESSURE

Problems in measuring arterial pressure focus accurately on three areas: (1) use of the correct size of cuff for each patient, (2) correct positioning of the patient during measurement, and (3) use of the correct phase of the Korotkoff sounds in measuring diastolic pressure.

The cuff size

It is generally agreed that hypertension in obese patients is overdiagnosed if the cuff is too small in relation to the arm circumference. When the arm circumference (AC) is less than 33 cm, a regular cuff (12 × 23 cm) should be used, a larger cuff (15 × 33 cm) if the AC is 33–41 cm and a thigh cuff (18 × 36 cm) if the AC is greater than 41 cm [88].

Position of the patient

Indirect arterial pressure should be measured with the cuff at the level of the heart. If it is above or below this level, the pressure in the brachial artery varies because of hydrostatic forces. Thus, standardization of posture and arm position is crucial. In the USA, it is recommended that arterial pressure is measured in the sitting position with the cuff at the level of the heart [92]. In the UK and in accordance with the ISSH [38], it is suggested that arterial pressure is measured with the patient lying on a bed or couch on the right side at 30 degrees of lateral tilt and with the sphygmomanometer cuff and heart at the same level.

Korotkoff sounds

Korotkoff sounds are produced by vibrations in the arterial wall as the pressure cuff is deflated. Phase I of the Korotkoff sounds defines systolic pressure. Diastolic pressure is defined by either phase IV (muffling of sounds) or V (disappearance of sounds). Phase IV is accepted by the ISSH and is generally used by midwives in the UK. Phase V is used in the USA. There is considerable controversy regarding whether K4 or K5 should be used in pregnancy. The reason why K4 has been adopted by many organizations appears to be based primarily on a study suggesting that a significant but undefined proportion of women have sounds audible down to zero cuff pressure [85]. This fact has not been sub-

Table 4 Definition of severe pre-eclampsia [145]

1. Arterial pressure > 160 mm Hg systolic or > 110 mm Hg diastolic on two occasions at least 6 h apart
2. Proteinuria > 5 g in 24 h or > 3+ on dipstick
3. Oliguria < 400 ml in 24 h
4. Cerebral signs—headache, blurred vision or altered consciousness
5. Pulmonary oedema or cyanosis
6. Epigastric or right upper quadrant pain
7. Impaired liver function
8. Hepatic rupture
9. Thrombocytopenia
10. HELLP syndrome

stantiated though it has been endorsed by leading authorities recommending the use of K4 [38].

DEFINITION OF HYPERTENSION

There is still controversy on the threshold level of arterial pressure at which the state of hypertension is said to be present. The ISSH defines hypertension in pregnancy as: (1) one reading of diastolic pressure exceeding 110 mm Hg, or (2) two consecutive diastolic arterial pressures of 90 mm Hg or greater at an interval of at least 4 h [38].

The definition is simple, precise and convenient, and it corresponds with statistical studies (a diastolic arterial pressure of 90 mm Hg correlates with approximately 3 standard deviations (SD) above the mean pressure in early and mid-pregnancy, 2 SD at 34 to 39 weeks and 1.5 SD at term) [37]. Furthermore, a diastolic pressure exceeding 90 mm Hg correlates with perinatal mortality [50]. In other proposed definitions [92, 106] it has been suggested that the degree of increase in diastolic pressure is important. Recently, it has been proposed that a combination of a first diastolic reading of less than 90 mm Hg, a subsequent increase of 25 mm Hg or more and a maximum diastolic pressure of 90 mm Hg or more may identify a group of pregnant women with pre-eclampsia more accurately than either the increase in pressure or absolute level [106]. However, there are limited epidemiological data on the clinical importance of increments in diastolic pressure and the use of two measurements of pressure makes this more complex; furthermore, there is a risk of misdiagnosis if the arterial pressure is abnormally low at any stage during early pregnancy.

Proteinuria is defined as the excretion of 0.3 g protein or more within 24 h or a measurement of 1+ or more using reagent strips or dipstick tests obtained from two samples of either 'clean-catch' or catheter samples of urine at least 4 h apart [38]. Proteinuria not only strengthens the diagnosis but it also indicates a poorer prognosis for both the mother and baby than when it is absent [91].

In the absence of trophoblastic disease, pregnancy-induced hypertension rarely occurs before 20 weeks' gestation. Hypertension and/or proteinuria diagnosed before 20 weeks usually results from pre-existing chronic hypertension or renal disease.

Pre-eclampsia is a progressive syndrome but unfortunately it is a very variable condition, and at any given time it is difficult to stage the condition or prognosticate on its progress.

Pragmatically, when managing patients with pre-eclampsia it is useful to be able to classify pre-eclampsia into mild or severe forms as the latter is associated with increased maternal and fetal morbidity and therefore more aggressive management is indicated. While many authors differ in their definitions it seems to be generally accepted that severe pre-eclampsia exists if one or more of the conditions described in table 4 are present.

Pathophysiology

Pre-eclampsia is a syndrome which affects virtually all maternal organ systems. The underlying pathophysiology is still not fully elucidated but the common pathological feature in the placenta, kidneys and brain is vascular endothelial damage and dysfunction [82], the major pathological changes are in the placental bed.

In normal pregnancy, the endothelium, internal elastic lamina and muscular layer of the media of the spiral arteries supplying the placenta are replaced by trophoblast and amorphous matrix containing fibrin [82]. These changes transform the vascular supply to a low pressure and high flow system which meets the needs of the fetus and placenta. Pre-eclampsia is associated with failure of, or incomplete trophoblastic invasion of, the spiral arteries resulting in narrowed spiral arteries and subsequent placental ischaemia. Subsequently, the abnormal placenta may release one or more factors which damage vascular endothelial cells throughout the mother (fig. 1) leading to multisystem dysfunction [108, 112] (fig. 2).

The endothelial cell has many important functions including maintenance of fluid compartments, prevention of intravascular coagulation, modification of contractile responses in the smooth muscle wall [51] and maintenance of immune and inflammatory responses. When injured, the endothelial cells not only lose these responses but also they produce procoagulants, vasoconstrictors and mitogens. Blood vessels in pre-eclamptic mothers demonstrate increased capillary permeability [51] with exaggerated responses to angiotensin II [39]. The increased pressor sensitivity leads to profound vasospasm and reduced organ perfusion changes which are characteristic of the disorder.

Many investigations have recorded maternal endothelial dysfunction in pre-eclampsia, e.g. maternal vascular prostacyclin production is reduced in patients with pre-eclampsia, probably because of endothelial dysfunction [82]. Other markers of endothelial damage include increased von Willebrand factor [105] and fibronectin levels [136]. Activated neutrophils release substances which can mediate vascular damage. These include contents of the neutrophil granules such as elastase and other proteases. Activation has been shown to occur in pre-eclampsia [53, 82]. In a recent study it has been shown that enhanced free radical formation occurs in patients with pre-eclampsia and this may augment endothelial damage and exacerbate the disease process [40] (see fig. 1).

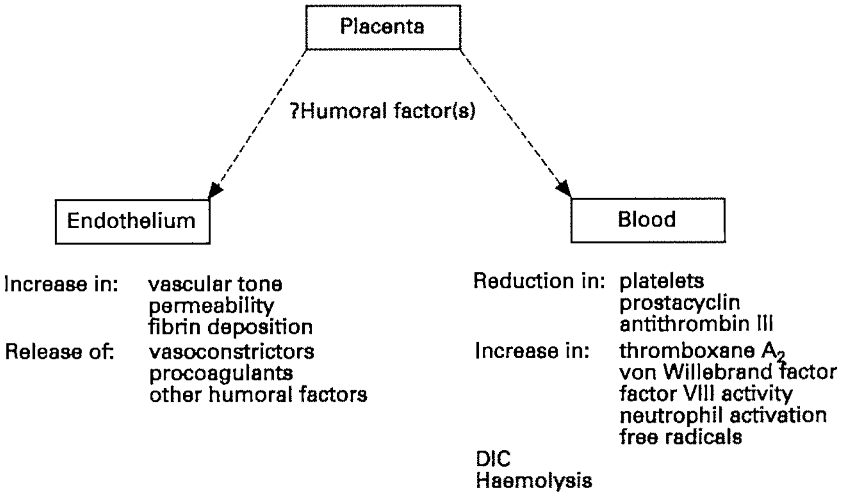

Figure 1 Major initiating changes in the aetiology of pre-eclampsia. The primary trigger may be placental ischaemia. (DIC = disseminated intravascular coagulation.)

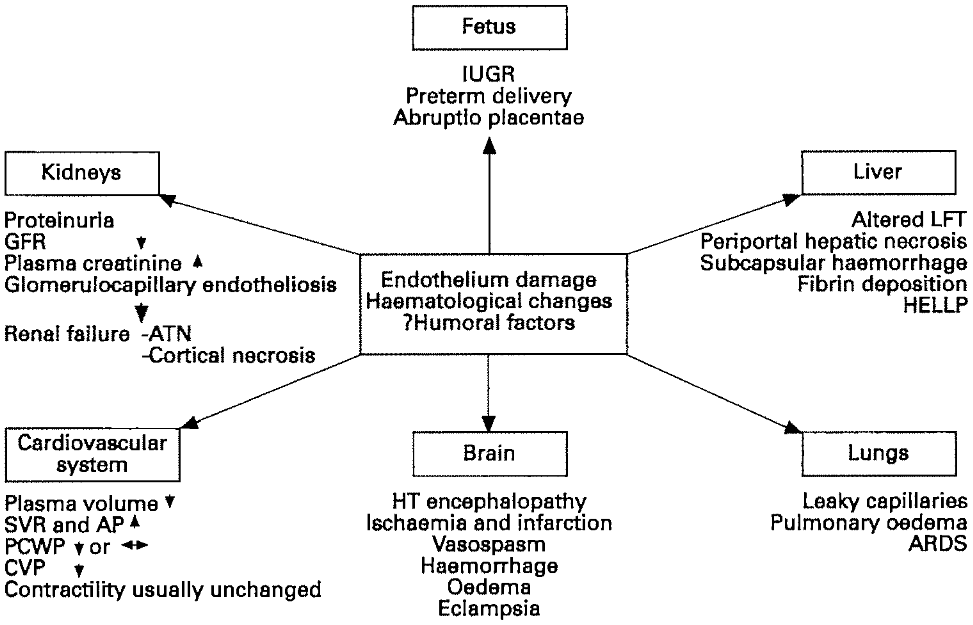

Figure 2 Multisystem changes occurring in pre-eclampsia. (GFR = glomerular filtration rate, ATN = acute tubular necrosis, SVR = systemic vascular resistance, AP = arterial pressure, PCWP = pulmonary capillary wedge pressure, CVP = central venous pressure, IUGR = intrauterine growth retardation, HT = hypertensive, LFT = liver function test, HELLP = haemolysis, elevated liver enzymes and low platelets, ARDS = adult respiratory distress syndrome.)

CARDIOVASCULAR SYSTEM

Hypertension is an early sign of pre-eclampsia and this may result partly from severe vasospasm. Typically, arterial pressure is unstable at rest and the circadian variation in arterial pressure variation is altered. Initially there is loss of the normal reduction in arterial pressure which occurs at night and subsequently, in severe cases, there is a reversed pattern with an increase in pressure during sleep. Responses to circulating adrenaline and noradrenaline are exaggerated. While normal pregnant women lose sensitivity to angiotensin II (which is a potent vasoconstrictor), patients with pre-eclampsia develop increased sensitivity to this hormone [39].

There have been a huge number of studies of the haemodynamic state in pre-eclampsia using both non-invasive [46, 87, 140] and invasive [11, 30, 32, 54, 83) techniques. Comparison of the findings of these studies is not easy because of large variation in patient population, severity of pre-eclampsia, type of therapy used for treatment, the stage of pregnancy or labour and the presence of concomitant medical disease such as chronic hypertension. In untreated patients with severe pre-eclampsia, studied with invasive monitoring [11, 32] it was found that cardiac index (CI) was either low or normal, systemic vascular resistance (SVR) was either normal or very high and pulmonary capillary wedge pressure (PCWP) was either low or normal. In treated patients [11, 32, 83] CI, SVR and PCWP were found to be normal to high. In women with severe pre-eclampsia, there is significant disparity between central venous pressure (CVP) and PCWP [32, 83].

There are several reports of reduced plasma volume in patients with pre-eclampsia as may be expected from the foregoing. In a review by Chelsey [21] it was suggested that the average plasma volume in pre-eclamptic women was 9 % lower than that of normotensive women and 30–40 % lower in patients with severe disease. However Sibai and colleagues [120] found that the plasma volume was normal in patients with mild disease. It is generally accepted that the decrease in the plasma volume is more obvious clinically in patients with severe disease.

In severe pre-eclampsia, plasma albumin is reduced as a result of loss in urine and loss across the leaky capillaries; consequently, colloid osmotic pressure (COP) is reduced [13]. Oian and colleagues [95] studied COP in patients with moderate and severe pre-eclampsia and found values of 20 mm Hg and 15 mm Hg in moderate and severe pre-eclampsia respectively compared with COP of 22 mm Hg in normotensive patients at term [13]. After delivery COP normally decreases as a result of fluid shift; typically in normotensive patients at 16–18 h post-delivery COP may be of the order of 16.2 mm Hg while in pre-eclamptic patients at this time, COP was as low as 13.8 mm Hg [146].

RESPIRATORY

Pulmonary oedema is not uncommon in pre-eclampsia. Sibai [123] found an incidence of 2.9 % in patients with pre-eclampsia and eclampsia; 70 % of the cases developed pulmonary oedema 71 h after delivery. It occurred more commonly in association with multiple organ dysfunction than as an isolated complication.

Pulmonary oedema occurs as a result of (a) a low COP in association with increased intravascular hydrostatic pressure, and (b) increased capillary permeability [14].

Colloid osmotic pressure and intravascular hydrostatic pressure

The colloid osmotic pressure (COP) is the pressure acting to prevent the movement of fluid out of the capillaries and the pulmonary capillary wedge pressure (PCWP) is a measure of the hydrostatic pressure operating in the opposite direction. Rackow and colleagues [99] studied 17 non-pregnant, critically ill patients with non-cardiogenic pulmonary oedema and found that a COP-PCWP difference of 4 mm Hg or less was always associated with pulmonary oedema. The COP in pre-eclamptic patients is lower than that in normotensive mothers [13] and typical pre-delivery/pre-treatment values of COP have been reported to range from 20 mm Hg in moderate pre-eclampsia to 15 mm Hg in severe pre-eclampsia [95] while PCWP values of > 12 mm Hg were found in 30 % treated patients with pre-eclampsia [32]. Increased hydrostatic pressure in pulmonary capillaries may occur as a result of left ventricular dysfunction, iatrogenic fluid overload and postpartum mobilization of extravascular fluid. In a group of women studied by Benedetti and colleagues [14], the most common cause of pulmonary oedema was alteration in hydrostatic-oncotic forces that occurred within 15 h postpartum and no patient had left ventricular dysfunction. The increase in PCWP in these patients (mean 18.6 mm Hg) was caused by mobilization of fluid from the extravascular to the intravascular compartment that normally occurs after delivery and also the effects of administering fluid with strong osmotic effects [14]. The use of colloids without adequate monitoring may increase the risk of pulmonary oedema.

Capillary permeability

The second most common cause of pulmonary oedema found in Benedetti's study was altered pulmonary permeability. The pathology underlying increased capillary permeability is not clear but it is probably endothelial cell damage. In this situation pulmonary oedema may be precipitated by acute fluid administration, amniotic fluid emboli or sepsis [4] and this may lead to adult respiratory distress syndrome (ARDS).

CENTRAL NERVOUS SYSTEM

The pathogenesis of eclampsia continues to be the subject of extensive investigations and speculation. The mechanisms suggested include vasospasm, ischaemia, haemorrhage, hypertensive encephalopathy, disseminated intravascular coagulation (DIC) and cerebral oedema [9]. Although the cerebral pathology of eclampsia resembles that of hypertensive encephalopathy with thrombosis, fibrinoid necrosis of cerebral arterioles, diffuse microinfarcts and petechial haemorrhages [23, 116], clearly hypertensive encephalopathy alone cannot account for all the central nervous system complications. While retinal haemorrhages, exudates and papilloedema are hallmarks of hypertensive encephalopathy, these changes are rarely encountered in eclamptics. In addition, at least 20 % of eclamptics do not have a systolic arterial pressure of > 140 mm Hg or a diastolic pressure of more than 90 mm Hg [51].

Magnesium sulphate, a known cerebral vasodilator, controls eclamptic convulsions very effectively and this lends support to the aetiology of cerebral vasospasm. Cerebral oedema was thought to be present in 20 % of patients dying with pre-eclampsia [80]. Diffuse cerebral oedema [69], haemorrhages [89] and infarcts [52] have been demonstrated in patients with eclampsia using computed tomography (CT) scanning. Most recently, magnetic resonance image (MRI) studies of brains of eclamptic women revealed focal changes characteristic of ischaemia [115]. Although the mechanism of convulsions is still controversial, it is likely that the aetiology depends on an interplay between vasospasm, microinfarcts and oedema.

Abnormal EEGs are frequent in pre-eclampsia [127]. The EEG pattern is usually a diffuse slow activity (theta or delta waves) sometimes with focal slow activity or paroxysmal spike activity but these are not pathognomic of pre-eclampsia as similar patterns are found in other conditions [127]. EEG abnormalities were thought to be related directly to the severity of maternal hypertension and may have explained claims that convulsions are secondary to cortical lesions developing after sudden increase in arterial pressure [44]. However Sibai and colleagues did not find any correlation between the degree of maternal arterial pressure elevation and the presence of EEG abnormality [127]. Hence a relationship between eclamptic convulsions and degree of maternal hypertension is questionable.

Visual disturbances in the form of photophobia, diplopia, scotomata, amaurosis or blurred vision are not uncommon in pre-eclampsia. Ischaemia caused by vasospasm of the posterior cerebral arteries or cerebral oedema in the occipital regions may be the cause of these visual disturbances [35].

Other neurological complications of pre-eclampsia include headache, hyperreflexia and clonus which are warning signs of increased cerebral irritation. Headache can occur in 40% of patients with pre-eclampsia and 80% of women who subsequently develop eclampsia [124]. Headache may be associated with nausea, excitability, apprehension and visual disturbances [119].

RENAL

The type of proteinuria in pre-eclampsia is non-selective; the increased permeability allows proportionally more larger molecular weight proteins such as transferrin and globulins to appear in the urine than occurs in renal disease with selective proteinuria [92]. The majority of women with pre-eclampsia have mild to moderately diminished renal perfusion and glomerular filtration with correspondingly elevated serum creatinine concentration. The decrease in glomerular filtration is caused partly by the glomerular swelling, narrowing of the glomerular capillary lumen and fibrin deposition in the endothelial cells (glomerular capillary endotheliosis). Although oliguria is common (i.e. urine output of < 20–30 ml h^{-1} over 2 h), progression to renal failure is rare. Acute tubular necrosis is often the cause of the reversible renal failure and this has a good prognosis [129]. Abruptio placentae, DIC and hypovolaemia usually precede the renal failure. Cortical necrosis, which is fortunately uncommon, causes permanent renal failure.

The renin-angiotensin-aldosterone system (RAAS) always seemed to provide a logical mechanism for the development of hypertension in pregnancy. Patients with pre-eclampsia have an increased response to angiotensin II [39]. However, this abnormal pressor response has been shown to be increased significantly by 22 weeks' gestation in patients who later develop pre-eclampsia. Despite extensive research, the role of the RAAS in pre-eclampsia is still unclear.

COAGULATION

Thrombocytopenia is a common finding in pre-eclampsia occurring in one-third of all patients [68]. Fortunately significant thrombocytopenia ($< 100 \times 10^9$ litre^{-1}) occurs in only 15% of women with severe disease [97]. This is caused by increased platelet consumption associated with low grade DIC [7]. Platelet activation is suggested by the findings of an inverse relationship between platelet count and fibrinogen degradation products, increased platelet specific protein β-thromboglobulin [7], and reduced platelet content of 5-hydroxytryptamine (5-HT). The thrombocytopenia is also thought to involve autoimmune mechanisms as evidenced by increased platelet associated immunoglobulin G levels. The effect of this thrombocytopenia on bleeding is not clear. Schindler [114] was unable to demonstrate a prolongation in bleeding time in patients with platelet counts below 100×10^9 litre^{-1}. However, other workers [104] reported a significant number of women with severe pre-eclampsia who had prolonged bleeding times despite an adequate platelet count. They showed that there was a good correlation between bleeding time and platelet count only when platelet count was lower than 100×10^9 litre^{-1}.

Table 5 The Collaborative Trial of Low Dose Aspirin [28]

Aim To investigate benefits of low dose aspirin (60 mg) and any fetal/neonatal or maternal side effects

Study

Multicentre

Large study (9634 patients)

Randomized, double blind and controlled

Results

	Aspirin	*Placebo*	*Significance*
Incidence of pre-eclampsia	6.7%	7.6%	ns
Birth weight (SD)	3024 (788)	2991 (810)	ns
Stillbirths/neonatal deaths	2.7%	2.8%	ns
Total neonatal mortality	4.3%	4.7%	ns
Preterm delivery	19.7%	22.2%	ns
Placental abruption	1.8%	1.5%	ns
Blood transfusion (mother)	4.0%	3.2%	S
Neonatal intraventricular haemorrhage	0.7%	0.9%	ns
Maternal deaths	3	1	ns

Conclusions

1. Routine prophylactic or therapeutic use of antiplatelet therapy for all women at risk of developing pre-eclampsia or IUGR is not recommended.
2. There is a small risk of increased peripartum haemorrhage.
3. Groups of patients who benefit: history of early onset pre-eclampsia and preterm delivery.
4. No increased neonatal morbidity or mortality.
5. No increased maternal mortality.

Maternal vascular prostacyclin is reduced in pre-eclampsia and platelet thromboxane A_2 production is increased. The resulting imbalance between prostacyclin and thromboxane is likely to contribute to the enhanced platelet activity and vascular damage. Aspirin inhibits cyclo-oxygenase, which is required for prostaglandin and thromboxane production, and therefore it reduces thromboxane generation and platelet activation. Aspirin also inhibits vascular prostacyclin production and this action may not be beneficial. However when given in low dose, aspirin may have selective actions and only block thromboxane production without affecting systemic vascular prostacyclin production because of lower concentrations of the drug in the systemic circulation compared with the portal circulation, the site of thromboxane inactivation. In addition, the nucleated vascular endothelial cells, unlike anucleated platelets, can synthesize new proteins and are therefore able to replace the inactivated thromboxane [56]. This provided the rationale for aspirin prophylaxis (table 5). The mechanism underlying prostacyclin deficiency is unclear.

In patients with mild pre-eclampsia, there are very small changes in the coagulation system detectable only by sensitive tests. Increased levels of fibrinopeptide, factor VIIIc activity, von Willebrand factor levels and reduced antithrombin III suggest activation of the coagulation cascade. Haemolysis may occur especially in association with abnormal liver function; these changes occur in the HELLP syndrome [143]. DIC occurs in 7 % of cases of severe pre-eclampsia or eclampsia [126] but the underlying cause is unclear.

HEPATIC

Pathological changes have been described by Sheehan and Lynch [116] in the livers of women dying of pre-eclampsia or eclampsia. The impaired liver function in severe pre-eclampsia can affect clearance of drugs metabolised by the liver. The cause of the hepatic dysfunction is not clear but it may result from periportal hepatic necrosis, subcapsular haemorrhages or fibrin deposition in hepatic sinusoids [6]. Spontaneous liver rupture is a rare but potentially lethal complication which carries a 60 % mortality [78]. Abnormal liver function tests may be part of the HELLP syndrome.

FETUS

Impairment of placental perfusion caused by placental disease and vasospasm is almost certainly the major reason for the high incidence of fetal loss, intrauterine growth retardation (IUGR), small-for-dates infants and perinatal mortality. In addition, the state of the mother frequently necessitates early termination of pregnancy and consequently, the incidence of respiratory distress syndrome is higher in neonates born to mothers with pre-eclampsia. Placental abruption is more common in pre-eclamptics [133] and is associated with a high perinatal mortality. It has also been found that there is a shift of the oxyhaemoglobin curve to the left in these patients and this decreases oxygen availability to the fetus [67].

Prediction of pre-eclampsia

Pre-eclampsia is the most important cause of maternal mortality in developed countries. Therefore, the prevention of pregnancy-induced hypertension is important for the sake of both mother and child. Prevention assumes both the ability to predict hypertension early enough to intervene and the existence of effective interventions. Without a practical early predictor, interventions cannot be developed.

During the past two decades more than 100 clinical, biophysical and biochemical tests have been reported in the literature to predict the development of pre-eclampsia [41]. However, the results of most studies have been inconsistent and contradictory. Currently, there is no ideal predictive test that fulfils all desired criteria.

The two most important predictive factors remain nulliparity and family history. Pre-eclampsia is present in 5.8 % of primigravidas but only 0.4 % of secundagravidas [84]. There is considerable evidence to support a significant genetic contribution to pre-eclampsia [29]. While several reports have established the likelihood of a recessive gene trait acting in pre-eclampsia, recent evidence on discordance among identical twins suggests that a single gene involvement is unlikely [139].

Arterial pressure in the second trimester and pressor tests have been investigated in the prediction of pre-eclampsia but there is such a large reported variation in their sensitivity and specificity as to render them of no predictive value.

Concentrations of a large number of constituents of blood and urine have been shown to change in pre-eclampsia including a high haemoglobin at first antenatal booking, elevated factor VIII-related antigen, reduced antithrombin III concentration, low platelet count and platelet AII binding. However, their proposals as predictors of pre-eclampsia have proved disappointing.

Doppler ultrasound studies of the deep lying arcuate arteries at 16–18 weeks' gestation may diagnose impaired trophoblastic invasion of the spiral arteries and may have potential in predicting pregnancies destined to become complicated by pre-eclampsia [134].

Prevention

The aetiology and pathophysiology of pre-eclampsia are still not understood fully and this has hindered development of effective preventive measures. So far, preventive strategies have concentrated on areas thought to be involved in the pathogenesis of pre-eclampsia, i.e. endothelium and prostaglandins.

ANTI-PLATELET THERAPY

Platelets appear to play a significant role in pathogenesis of pre-eclampsia and early small-scale studies suggested that aspirin may be effective in preventing pre-eclampsia [60] especially in reducing the more severe complications of intrauterine growth retardation and the risk of pregnancy-induced hypertension, with no observed risk of neonatal and maternal adverse effects. However these benefits were not consistently observed in other studies [62, 121]. Unfortunately, these studies were not large enough to provide definite evidence as to the safety and efficacy of prophylactic aspirin during pregnancy. The recent Collaborative Low Dose Aspirin study (CLASP) [28] was designed to overcome the weakness of previous studies. This was a large multicentre trial (table 5). The results were disappointing in that aspirin did not affect significantly the incidence of proteinuria, eclampsia, IUGR, stillbirths or neonatal deaths. The use of aspirin was associated with a reduction of only 12 % in the incidence of pre-eclampsia which was not significant. It was concluded that the routine prophylactic use of aspirin or antiplatelet treatment in all women who are at risk of developing pre-eclampsia is not justified. Low dose aspirin may be justified only in women thought to be especially liable to early onset pre-eclampsia severe enough to need preterm delivery. In such women, it seems appropriate to start low dose aspirin in the second trimester. The use of aspirin was associated with increased requirement for postpartum blood transfusion [28] and a higher incidence of abruptio placentae [121].

MAGNESIUM AND ZINC

Although magnesium supplementation has been suggested as a possible means of reducing the incidence of pre-eclampsia [132] clinical trials have yielded conflicting results [15, 132] and the current recommended daily allowance of 320 mg per day should not be exceeded. Zinc has also been studied but there are no convincing data for any efficacy.

FISH OILS

Fish oils are a source of long chain n-3 unsaturated fatty acids that yield eicosapentaenoic acid for the synthesis of thromboxane A_3 and prostacyclin I_3 instead of thromboxane A_2 and prostacyclin I_2 derived from arachidonic acid. These substances therefore shift the balance of platelet reactivity towards inhibition of aggregation and increased vasodilatation [107]. However, large controlled multicentre trials need to be organized to assess any beneficial or negative effects of fish oil supplementation in pregnancy.

CALCIUM

There is an inverse relationship between calcium intake and hypertensive disorders of pregnancy [12] and until recently it was thought that calcium supplements cause a significant reduction in the incidence of gestational hypertension but not pre-eclampsia itself. However, more recent studies have demonstrated that calcium supplements reduced the incidence of hypertension, pre-eclampsia and preterm delivery [18, 141]. Again controlled trials are needed to confirm if there is any significant reduction in perinatal mortality in order to recommend routine use of calcium supplements during all pregnancies.

REPEATED EXPOSURE TO SPERM

Recently, Robilhand [109] has reported data from a prospective study suggesting that pre-eclampsia may be prevented by increasing the duration of sexual cohabitation before the first pregnancy with that partner. The overall incidence of pregnancy-induced hypertension in their study decreased from 10.6 % in the general population to 5.1 % in women with more than 12 months' cohabitation before conception. They suggested that protection may be induced by an immune response in the female to repeated exposure to antigens on the sperm.

Treatment

In the absence of complete understanding of the pathogenesis of the syndrome, management is based mainly on treatment of symptoms and signs of the secondary effects of pre-eclampsia and it is designed to reduce maternal and fetal complications. The management of these patients should ideally be multidisciplinary and the anaesthetist should be involved in the care of patients with severe pre-eclampsia at an early stage. In addition to deciding when (table 6) and how to deliver, management should include treatment of hypertension, oliguria and fluid therapy, coagulation abnormalities and convulsions.

Table 6 Severe pregnancy-induced hypertension—indications for delivery (DIC = disseminated intravascular coagulation, IUGR = intrauterine growth retardation)

1. Patient at term or at a gestation where viability of the fetus is not a concern
2. At any stage of pregnancy for:
    - Maternal complications such as:
        - renal failure
        - hepatic disorder
        - falling platelets or DIC
        - HELLP syndrome
        - eclampsia
    - Fetal complications
        - chronic fetal compromise:
            - IUGR
            - Oligohydramnios
            - Doppler abnormalities
        - acute fetal compromise
            - Cardiotocographic abnormalities
            - Placental abruption

TREATMENT OF HYPERTENSION

Cerebral haemorrhage is a major cause of maternal deaths (60 %) from pre-eclampsia or eclampsia [42]. When mean arterial pressure (MAP) exceeds 140 mm Hg (equivalent to 180/120), there is a significant risk of maternal cerebral vascular accident (CVA) [90]. Therefore, it is recommended that arterial pressures of greater than 170/110 should be treated with urgency with the aim of maintaining pressure below 170/110 but above 130/90. The aim should be to prevent intracerebral haemorrhage while not affecting uteroplacental blood flow and maternal renal function. Precipitous reductions in arterial pressure should be avoided by adequate volume expansion before the use of vasodilators. Prolonged treatment of hypertension is advisable when the fetus is immature in an attempt to delay delivery to allow further maturation. However, this can only be undertaken provided the mother is not placed at increased risk and that strict monitoring of both the mother and the fetus is carried out at frequent regular intervals. Hospitalization and bed rest may be all that are required in some patients but it has been suggested that this has little effect on arterial pressure [47].

Prolonged therapy

Many antihypertensive drugs have been used including methyldopa, β-blockers and nifedipine. ACE inhibitors are associated with toxic effects in the fetus in both animals and humans [55] and are therefore contraindicated.

Methyldopa, a centrally acting drug which reduces sympathetic outflow, is effective in maintaining arterial pressure at a safe level in the majority of women with pre-eclampsia [90] and in reducing the frequency of severe hypertensive episodes. However, because pre-eclampsia is a progressive disorder, methyldopa may eventually fail to provide adequate control. In this situation, another antihypertensive may be used and plans made for the delivery of the baby. Methyldopa is the only antihypertensive drug with documented long-term safety for the newborn. It is usually given in an initial dose of 1 g day^{-1} in three to four divided doses and may be increased to 3 to 4 g day^{-1}. Methyldopa appears to reduce the small risk of mid-trimester abortions seen in association with early hypertension.

Labetalol has theoretical advantages particularly for the uteroplacental vasculature because of its α-blocking properties. It provides adequate control of arterial pressure but long-term fetal/neonatal effects have not yet been evaluated adequately. There is concern that β-blockers may impair the capacity of the fetus to cope with intrauterine stress. In one trial [17] atenolol was associated with growth retardation when started early in pregnancy for essential hypertension. Clinical studies on the chronic administration of nifedipine in pregnancy are limited. Nifedipine given either as first line treatment [61] or as second line treatment [76] was effective in controlling arterial pressure in most patients. However, there are limited data on its effects on the fetus or neonate.

Acute therapy

A large number of agents have been used for acute control of arterial pressure but hydralazine is the most widely used agent. Its main advantage is the extensive experience of its use. It may be given either as intermittent bolus doses (5–10 mg every 20 min) or as a continuous infusion (5–20 mg h^{-1}) following an initial 5 mg bolus [90]. The onset of action of hydralazine is 20–30 min; this must be appreciated because if sufficient time is not allowed between injections, hypotension can occur. One of the drawbacks of hydralazine is that its side effects (headache, tremor and vomiting) mimic the symptoms of impending eclampsia.

Labetalol is a combined α- and β-blocking agent, with a relatively rapid onset of action causing maximal effects within 20 min after 50 mg i.v. bolus or 30 min after 100 mg administered orally. These boluses may be repeated at intervals of 20 to 30 min as necessary. Labetalol may also be given as a continuous infusion at 20 to 160 mg h^{-1}. Labetalol appears to be a satisfactory alternative to hydralazine and it may be preferable because of relative freedom from maternal side effects. However, there is less experience with its use particularly in relation to effects on the fetus and neonate. It is also contraindicated in asthmatic patients. Hypotension, oliguria and bradycardia have been reported occasionally in neonates when the drug was given in the presence of fetal distress or hypoxia [144]. The use of β-blockers in severe pre-eclampsia impairs the capacity of the fetus to cope with intrauterine stress and it may attenuate the usual signs of fetal distress.

Nifedipine is used widely for the management of acute and chronic hypertensive non-obstetric patients. Although it is unlicensed for use in pregnancy [86] it has been shown to be satisfactory in the management of hypertension in pregnancy [76]. Experience with its use is limited and it requires further careful monitoring. Two oral preparations of nifedipine are available which act rapidly; nifedipine capsules within 10–15 min and nifedipine slow release tablets within 45 to 60 min with a more prolonged effect. Nifedipine has also been given sublingually; a dose of 5 mg was found to maintain uteroplacental blood flow despite a reduction in arterial pressure and uterine perfusion pressure [77]. In this study, pregnancy outcome was not discussed, but there was no evidence of fetal distress. Nifedipine should be used with caution if magnesium sulphate ($MgSO_4$) is being given concurrently as potentiation may occur leading to profound hypotension [142].

Other antihypertensives which are used less frequently include diazoxide, sodium nitroprusside (SNP) and glyceryl trinitrate (GTN). Their hypotensive effects occur rapidly and there is a considerable risk of excessive hypotension and reduced uteraplacental blood flow. GTN is administered as a continuous infusion at an initial rate of 10 μg min^{-1} and titrated against response. There is a risk of methaemoglobinaemia if a dose of 7 μg kg^{-1} min^{-1} is exceeded. SNP is given at an initial rate of 0.25 μg kg^{-1} min^{-1} and increased according to response. Worries about fetal cyanide toxicity and death observed in previous animal studies discouraged its use, but more recent studies have failed to reveal evidence of cyanide accumulation in the fetus [49]. Direct arterial pressure measurement is recommended whenever GTN or SNP is used.

FLUID THERAPY

Pre-eclampsia is associated with a reduction in intravascular volume, haemoconcentration and hypoproteinaemia but pulmonary oedema occurs in some cases of pre-eclampsia and therefore there is some controversy on optimum fluid therapy.

It is generally accepted that plasma volume should be corrected by volume expanders before vasodilatation with either drugs or extradural analgesia/anaesthesia. Hypotension and fetal distress were reported in patients who had extradural analgesia or hydralazine without appropriate fluid therapy [20]. The question therefore is often not whether to give fluid but what type, how much, how rapidly and with what level of monitoring.

The crystalloid–colloid controversy is still debated in the management of pre-eclamptic patients because the condition is complicated by both low COP and leaky capillaries and they are therefore at risk of developing non-cardiogenic pulmonary oedema [123]. Administration of colloid solution may increase COP transiently but there is no evidence to suggest that this improves clinical outcome. Crystalloids may be given instead at a rate of 1–2 ml kg^{-1} h^{-1} and altering subsequent fluid therapy according to the patient's clinical condition and urine output in addition to CVP and PAWP measurements where necessary. Infusion of crystalloid alone decreases oncotic pressure further [146], while the use of colloid such as albumin may result in high CVP and PAWP values and the onset of pulmonary oedema particularly in the postpartum period [71]. If pulmonary oedema develops, it requires treatment by conventional medical therapy including oxygen, diuretics, reduction in preload/afterload, fluid restriction and intermittent positive pressure ventilation.

It is not clear what constitutes ideal CVS monitoring of patients with pre-eclampsia but one can safely state that the level of monitoring required should be tailored to each patient. Joyce and colleagues [66] evaluated the effects of fluid loading in pre-eclampsia patients with a low CVP (-1 to -4 cm H_2O) before extradural block. They found it necessary to give 750 ml plasmanate and 2 litre Ringer lactate in order to achieve CVP values of $+6$ cm H_2O. This regimen was associated with a high postpartum CVP (16–18 cm H_2O) and several cases of pulmonary oedema. It is now recognized that on occasions there may be a poor correlation between CVP and left atrial pressures [32]. Benedetti and colleagues [14] found no correlation between CVP and PCWP when the CVP exceeded > 6 mm Hg. Common indications for a CVP catheter include oliguria, impending or established pulmonary oedema and signs of severe pre-eclampsia. Because these patients may have a coagulation abnormality, it may be preferable to insert a central venous catheter via a peripheral site such as the antecubital fossa.

Insertion of a pulmonary artery catheter allows measurement of PCWP, CO and SVR. In severe pre-eclampsia PCWP is usually normal or low and in this situation, with good left ventricular function and high SVR, infusion of fluids allows the use of vasodilators and improves renal output [26]. However, if the PCWP is high with or without poor LV function, volume therapy may need to be carefully controlled. Insertion of a PAP catheter is associated with maternal morbidity and mortality [20] especially in these patients who may have coagulation abnormalities. Criteria recently proposed for pulmonary artery (PA) catheterization in patients with severe pre-eclampsia [27] include: patients failing to respond to antihypertensive treatment, pulmonary oedema, unresponsive oliguria and where extradural anaesthesia is contemplated. Many experts believe that these criteria are too broad and that there are few indications for a PA rather than a CVP catheter.

TREATMENT OF OLIGURIA

The pathogenesis, definition and management of oliguria in severe pre-eclampsia is still not well defined. The definitions of oliguria used in clinical practice include a urine output of < 30 m h^{-1} for 3 h, < 30 ml h^{-1} for 2 h, < 0.5 ml kg^{-1} h^{-1} for 2 h, < 500 ml 24 h^{-1} or < 100 ml 4 h^{-1}. The diagnosis of oliguria should be based on at least a 4-h period. Many patients with a transient decrease in urine output to < 30 ml h^{-1} often resume normal urine output spontaneously without any therapy [122]. Poor renal function in these patients has a good prognosis [129].

The oliguric patient may be treated with a fluid challenge of 500 to 1000 ml crystalloid. Lee and colleagues [73] showed in seven patients that oliguria was a poor index of volume status in patients with pre-eclampsia. If there is no response to a fluid challenge, the CVP should be monitored in the knowledge that this does not always correlate with PCWP when CVP is > 6 mm Hg [14]. Repetitive unmonitored fluid administration should be avoided as this may lead to pulmonary oedema especially in the postpartum period [14].

The use of dopamine in pre-eclampsia has not been widely investigated. Kirshon and colleagues [70] studied the effects of low dose dopamine (1–5 μg kg^{-1} min^{-1}) in six oliguric patients. Cardiac output increased from 6.8 (SD 1.8) to 8.0 (2.3) litre min^{-1}, while arterial pressure, CVP and PCWP did not change significantly. Urine output increased from 21 (10) to 43 (23) ml h^{-1} and there were no adverse maternal or fetal side effects.

Nifedipine 10 mg orally every 4 h has been shown to increase urine output significantly in the postpartum period [8]. Although the mechanism of action is unknown, it may be related to increased renal blood flow.

MANAGEMENT OF ECLAMPSIA

Because the pathogenesis of eclamptic convulsions is still poorly understood it is not surprisingly that there is disagreement on how to treat the condition. In the past, most clinicians agreed that diazepam was appropriate but this view has been challenged recently [137]. Chlormethiazole has become less popular because of the need to administer large volumes of fluid and because of the ease of oversedation with loss of airway reflexes. Phenytoin achieved popularity because of lack of sedative side effects and it has been the agent of choice in the UK.

Table 7 The Collaborative Eclampsia Trial [137]. Comparison of magnesium sulphate (M), diazepam (D) and phenytoin (P) in the treatment of eclampsia. S = significant, NS = non-significant differences.

Aim To compare $MgSO_4$, diazepam and phenytoin in the treatment of eclampsia

Study Multicentre, randomized, large (1680 patients)

Results	*M* (%)	*D* (%)	*S*	*M* (%)	*P* (%)	*S*
Recurrent fits	13.2	27.9	S	5.7	17.1	S
Maternal mortality	3.8	5.1	NS	2.6	5.2	NS
Perinatal mortality	24.8	22.4	NS	26.1	30.7	NS
Ventilation	5.5	6.0	NS	14.9	22.5	S
Respiratory Depression	7.7	7.3	NS	8.2	11.6	NS
Pneumonia	2.0	3.1	NS	3.9	8.8	S
ITU admissions	14.3	16.6	NS	16.7	25.1	S
Blood transfusions	15.1	20.1	NS	19.7	27.0	S
Neonatal intubations	11.3	15.7	NS	12.7	23.9	S
SCABU admissions	46.5	50.2	NS	31.7	43.6	S

Conclusions

1. $MgSO_4$ should be the drug of choice for eclampsia
2. Phenytoin caused more maternal and neonatal morbidity
3. Diazepam and phenytoin had more recurrent convulsions compared with $MgSO_4$

Table 8 Use of $MgSO_4$ in eclampsia

Loading dose
  i.m. 4 g i.v. plus 5 g i.m. in each buttock
  i.v. 4–6 g i.v.
Maintenance
  i.m. 5 g i.m. every 4 h
  i.v. 1–2 g h^{-1} infusion
Toxicity
  4.0–6.5 mmol $litre^{-1}$
    nausea and vomiting
    somnolence
    double vision
    slurred speech
    loss of patellar reflex
  6.5–7.5 mmol $litre^{-1}$
    muscle paralysis
    respiratory arrest
  > 10 mmol $litre^{-1}$
    cardiac arrest

Magnesium sulphate was first suggested in 1906 and has been the main choice in the USA for over 60 years [117] and also in South Africa. However, until very recently, there had been little controlled evidence on the choice of anticonvulsants. Many previous studies were either too small or inconclusive [33, 43].

In the recent collaborative eclampsia trial [137], mothers allocated to receive $MgSO_4$ had a significant lower risk of recurrent convulsions than those allocated to either diazepam or phenytoin (table 7). Maternal mortality was lower (although non-significantly) among women who received $MgSO_4$ and in this group they were less likely to be admitted to ITU, less likely to undergo ventilation or have chest infections compared with the phenytoin group but there was no difference compared with the diazepam group. This large randomized and controlled multicentre study may be the turning point for the use of $MgSO_4$ in eclampsia in the UK.

$MgSO_4$ is not an anticonvulsant and its mode of action is not clearly understood. It is thought to reverse cerebral vasoconstriction [10], by blocking calcium influx through the NMDA (*N*-methyl-D-aspartate) subtype of glutamate channel [31]. $MgSO_4$ is given either i.v. or i.m. and the aim is to achieve a therapeutic concentration of 2–3.5 mmol $litre^{-1}$ [24] (table 8). Plasma concentrations exceeding 4 mmol $litre^{-1}$ cause toxicity which may be treated with i.v. calcium gluconate 1 g. Patients with poor renal function require a slower rate of infusion of $MgSO_4$ and closer monitoring of the patient for any signs of toxicity. When using $MgSO_4$, monitoring of the patients should include regular measurements of plasma concentrations of magnesium and assessment of tendon reflexes for hyporeflexia.

Are prophylactic anticonvulsants indicated?

Eclampsia occurs in women with established pre-eclampsia but in 38 % of cases, it occurs with no earlier warning. Predicting if an individual woman will develop eclampsia is difficult and this has contributed to the wide variation in the use of prophylactic anticonvulsants. The problem of prediction has been obviated in some units by treating all women with advanced pre-eclampsia with anticonvulsants. However, this is considered undesirable because it greatly increases the risks of major side effects. Chua and Redman have suggest that treatment should be reserved for those who have had their first convulsion [25]: 99 % of the units in USA use prophylactic $MgSO_4$ in all women with pre-eclampsia in labour [19]. Some units reserve prophylactic anticonvulsants for patients with impending eclampsia (visual disturbances, headache, increased reflexes and clonus). In the UK, 16 % of units do not prescribe prophylactic anticonvulsants [59]. Prophylactic anticonvulsants are only worthwhile if the benefit outweighs the harm from the side effects. There are few studies which have investigated prophylactic use of anticonvulsants in pre-eclampsia. Some studies comparing $MgSO_4$ with phenytoin [5, 81] had conflicting results. Studies comparing $MgSO_4$ with no treatment were too small to provide any conclusions [10, 22]. Therefore the debate on the benefit of prophylactic anticonvulsants will continue until large randomized studies comparing $MgSO_4$ and placebo are carried out.

HELLP syndrome

Pritchard and colleagues [98] first described an association of coagulation and liver enzyme abnormalities with pre-eclampsia in 1954 and Weinstein in 1982 coined the term HELLP [143] (haemolysis, elevated liver enzymes and low platelets).

The HELLP syndrome complicates 0.3 % of all pregnancies and between 4 and 20 % of those with severe pre-eclampsia [125, 138]. Maternal and fetal outcomes are poor with maternal mortality of up to 24 % and perinatal mortality of 33 % [128]. Thirty per cent of the cases occur in the postpartum period [125]. The clinical signs and symptoms include epigastric pain, upper abdominal tenderness, proteinuria, hypertension, jaundice, nausea and vomiting. The disease may progress to haematuria, oliguria, acute tubular necrosis, cortical necrosis and panhypopituitarism. Complications of HELLP syndrome are summarized in table 9. Laboratory investigations reveal thrombocytopenia, abnormal liver function tests, elevated plasma concentrations of haptoglobin and haemolytic anaemia. Sibai [125] suggested that the following standardized laboratory values be used to diagnose HELLP syndrome: (1) haemolysis, defined by abnormal peripheral blood smear, (2) increased bilirubin ($\geqslant$ 1.2 mg dl^{-1}) or increased lactate dehydrogenase ($\geqslant$ 600 u. $litre^{-1}$),

Table 9 Complications of HELLP syndrome (n = 442) [125]

1.	Maternal mortality	1.1 %
2.	Disseminated intravascular coagulation	21 %
3.	Abruptio placentae	16 %
4.	Acute renal failure	7.7 %
5.	Pulmonary oedema	6.0 %
6.	Subcapsular liver haematoma	0.9 %
7.	Retinal detachment	0.9 %
8.	Laparotomies for intra-abdominal bleeding	2.0 %
9.	Pleural effusion	6.0 %
10.	Adult respiratory distress syndrome	1.0 %
11.	Cerebral oedema	1.0 %
12.	Transfusion of blood products	55 %

(3) increased serum aspartate aminotransferase ($\geqslant$ 70 u. litre^{-1}), (4) low platelets defined as platelet count $< 100 \times 10^9$ litre^{-1}. Aggressive treatment is necessary and delivery should be carried out by Caesarean section if necessary [119]. Vaginal delivery is not contraindicated [118] but fetal thrombocytopenia in 20% of cases may make this hazardous [138]. Platelet transfusion is recommended if the platelet count is $< 20 \times 10^9$ litre^{-1} for vaginal delivery and $< 50 \times 10^9$ litre^{-1} for Caesarean section [118]. A transfusion of fresh whole blood is recommended if the haemoglobin is less than 10 g dl^{-1}. The bladder should be catheterized to monitor hourly urine output. Central venous pressure monitoring is usually necessary preferably via a peripheral vein. The choice of anaesthetic technique depends on the condition of the patient and fetus. Regional techniques may be contraindicated because of coagulation disturbances. The drugs used should have minimal hepatic and renal metabolism. Blood glucose should be monitored as severe hypoglycaemia has been reported in the HELLP syndrome [48].

Anaesthesia and analgesia in patients with pre-eclampsia

Extradural analgesia is preferred by most anaesthetists for providing pain relief in labour and anaesthesia for operative delivery provided that there are no contraindications. Ramanathan [102], found that extradural anaesthesia was associated with smaller maternal haemodynamic and neuroendocrine stress responses during elective Caesarean section in women with severe pre-eclampsia compared with general anaesthesia. Extradural anaesthesia also avoided the transient neonatal depression seen after general anaesthesia. In another study in patients with severe pre-eclampsia, lumbar extradural analgesia was found to reduce MAP from 121.4 to 97.7 mm Hg without altering CI, PVR, CVP or PCWP [93]. Provided that the patient has been preloaded with fluid (crystalloid 500 ml), and that supine hypotension is avoided, extradural analgesia has been found to increase intervillous blood flow. Ephedrine is safe to use in these patients as it does not adversely affect uterine blood flow [32]. The choice of local anaesthetic does not seem to be critical as bupivacaine 0.25% and 0.5%, lignocaine 2% and chlorprocaine 2% have been used without adverse effects [1, 64, 101]. The pharmacokinetics of lignocaine in pre-eclampsia differ from those in normotensive patients; total body clearance is prolonged and resulting in higher blood concentrations [1], probably because of the impaired liver function. It is recommended that adrenaline is avoided as these patients have increased plasma catecholamine levels. When extradural analgesia is used for pain relief during labour a mixture of an opioid and a local anaesthetic administered as an infusion is preferred as this gives continuous pain relief and less hypotension compared with intermittent boluses of local anaesthetic.

Spinal anaesthesia is often discouraged in patients with pre-eclampsia because of the risk of severe hypotension. In a retrospective study by Hood and Boese [58] comparing extradural and spinal anaesthesia for elective Caesarean section in patients with severe pre-eclampsia, there was a slightly greater reduction in arterial pressure in women who received spinal anaesthesia. However, the authors remarked that the difference between the two groups was only nearly statistically significant ($P < 0.052$) and that spinal anaesthesia is not as unsafe as generally thought. However, this retrospective study involved only 34 patients in the extradural group and 14 in the spinal group. A larger prospective study would be required before spinal anaesthesia can be recommended as being safe for patients with pre-eclampsia.

Thrombocytopenia is common in patients with pre-eclampsia and this may contraindicate regional analgesia. However, there is considerable debate on the reliability of platelet count in predicting the risk of extradural haemorrhage. A platelet count of > 150–400×10^9 litre^{-1} is generally accepted as normal but this may not be true during pregnancy. Previous studies have shown platelet count of less than 150×10^9 litre^{-1} in 6.4% of randomly selected healthy pregnant women. The current belief that extradural analgesia is contraindicated in women whose platelet count is less than 100×10^9 litre^{-1} has no experimental supporting data. Bleeding time and thrombelastography are better measures of platelet function than platelet count and should be used when there is any doubt. The disadvantage of the bleeding time is that most laboratories offer this test during limited hours, there is a significant inter- and intra-technician variability and there is lack of controlled evidence indicating that the use of bleeding times avoids extradural or spinal bleeding [20]. Some units do not routinely order bleeding time unless the platelet count is less than 80×10^9 litre^{-1} or if there is clinical and laboratory evidence of coagulopathy [75]. Other workers recommend that an extradural should not be used if platelet count is less than 80×10^9 litre^{-1} [110]. However it is important to balance the risk of bleeding into the extradural space against the relative risk of general anaesthesia in these patients. Unfortunately, to date there is no single reliable test to indicate the risk of bleeding into the extradural space.

GENERAL ANAESTHESIA IN PATIENTS WITH PRE-ECLAMPSIA

Regional anaesthesia is undoubtedly safer for patients with pre-eclampsia but general anaesthesia may be necessary when fetal distress requires immediate delivery or on occasions when regional analgesia has either failed or is contraindicated. General anaesthesia in patients with pre-eclampsia presents risks to the mother and baby. The hazards of general anaesthesia include: (1) potentially difficult intubation, laryngeal oedema may not become apparent until laryngoscopy [16], (2) potential aspiration of gastric contents, (3) difficulties related to neuromuscular blockers, (4) pressor response to laryngoscopy and intubation, and (5) impaired intervillous blood supply [65].

PROBLEMS WITH INTUBATION

Laryngeal oedema is a rare but potentially serious complication of pre-eclampsia. It often occurs as part of the general oedema and facial swelling but occasionally it occurs with few warning signs. It is, therefore, necessary to be prepared for a difficult intubation in these patients, to have a wide range of size of tracheal tubes and to avoid repeated intubations as this may worsen the oedema. As laryngeal oedema may also develop during the intraoperative period [111], anaesthetists need to take care when extubating the tracheae of these patients. Before extubation, the cuff should be deflated and air passing the tracheal tube is assessed by occluding the tracheal lumen and allowing the patient to breathe around the tube as suggested by Potgieter and Hammond [96].

PRESSOR RESPONSE TO INTUBATION AND EXTUBATION

The pressor responses to laryngoscopy, intubation and extubation may increase the risks of cerebrovascular accidents, increase myocardial oxygen requirements, induce cardiac arrhythmias, induce pulmonary oedema and reduce uterine blood flow. Many drugs have been used in an attempt to attenuate these responses. Hydralazine is ineffective [100] while labetalol in doses up to 1 mg kg^{-1} (given in 10–20 mg boluses) has been shown to cause a moderate reduction in MAP and heart rate at intubation [103]. A newer β-blocker, esmolol, is currently under investigation; it has a rapid onset of action and shorter duration of action and may prove to be useful not only for intubation but also extubation. Short-acting opioids have also been used at induction of anaesthesia [36]. Although the neonate's condition at birth is generally an important consideration in choice of anaesthetic agent, in pre-eclampsia and eclampsia, the condition of the mother is always the anaesthetist's primary concern [57]. Fentanyl 2.5 μg kg^{-1} has been compared with alfentanil 10 μg kg^{-1}; while both drugs reduced the pressor response to intubation they did not abolish it [113] possibly as a result of inadequate dosage. Fentanyl 200 μg and droperidol 5 mg were found to obtund the hypertensive response to intubation [72], $MgSO_4$ has been used to control both catecholamine release and the pressor response [63]. It was found that pre-treatment with $MgSO_4$ 40 mg kg^{-1} appeared to be superior to either lignocaine or alfentanil [3]. Other drugs which have been used in this situation include lignocaine, SNP [135], GTN [79] and trimetaphan [131]. Calcium channel blockers such as nifedipine are currently being investigated.

PROBLEMS WITH NEUROMUSCULAR BLOCKERS

Where the mother has received $MgSO_4$, the non-depolarizing neuromuscular blockers are potentiated and they should be used with caution. $MgSO_4$ inhibits calcium facilitated pre-synaptic transmitter release hence enhancing sensitivity to non-depolarizing neuromuscular blockers [130]. Fasciculations may not occur after administration of suxamethonium to a mother treated with $MgSO_4$.

SHORT COMMUNICATIONS

Extradural and subarachnoid catheterization using the Seldinger technique

E. M. DELHAAS

Summary

The Seldinger technique was developed using a plastic introducer through which introduction and manipulations of a silicone spinal catheter, an extradural stimulation lead or a small diameter fibreoptic scope are possible without the risk of damage to the vulnerable devices. It is not intended as a replacement of the standard technique of introducing a spinal catheter through a Tuohy needle in general anaesthetic practice. Silicone spinal catheters and stimulation leads are used for long-term therapy in intractable chronic pain and spasticity. A fibreoptic scope is used for endoscopic examination of the subarachnoid or extradural space. Using a standard Tuohy needle the soft silicone extradural lead can be damaged easily by manipulations during insertion. For this reason the manufacturer modified the Tuohy needle for extradural silicone lead introduction. The disadvantages of this modified Tuohy needle are: first, difficulty in localization of the extradural space, second, the needle is unsuitable for a subarachnoid catheter or introduction of a fibreoptic scope. The Seldinger technique was performed 25 times in 18 patients, introducing a spinal silicone catheter ($n = 14$), an extradural silicone stimulation lead ($n = 2$) or a small diameter fibreoptic endoscope ($n = 9$). Paraesthesiae caused by neural irritation occurred in awake patients. This did not differ from the technique using a Tuohy needle only. Neural damage or trauma did not occur with the Seldinger technique. The incidence of post-spinal headache was the same for both techniques. No further complications were noted. (*Br. J. Anaesth.* 1996; **76**: 149–150)

Key words
Anaesthetic techniques, subarachnoid. Equipment, catheters extradural. Equipment, catheters subarachnoid.

Implanted drug delivery systems are used for managing intractable chronic pain and spasticity with continuous subarachnoid drug infusion [1, 2]. Long-term experience shows a rather high spinal catheter complication rate [2]. One of the problems is damage to the silicone spinal catheter during insertion. This could be caused by the sharp edges of the Tuohy needle and it is possible that this may completely cut the catheter resulting in a catheter segment remaining in the subarachnoid space.

Advancing a lead for spinal cord stimulation or a small diameter fibreoptic endoscope [3] through a Tuohy needle is potentially hazardous. For this reason, the manufacturer has modified the Tuohy needle for extradural silicone lead introduction. The disadvantages of this modified Tuohy needle for extradural lead introduction are: first, difficulty in localization of the extradural space and second, the needle is still unsuitable for use with a subarachnoid silicone catheter or fibreoptic scope.

When using a paramedian approach for subarachnoid catheterization, less damage to the catheter can be expected than with the classic median approach. However, the risk of damage to the catheter cannot be completely avoided.

This study was designed to determine the usefulness of the Seldinger technique [4] which allows insertion of a catheter, lead or fibreoptic scope through a plastic sheath into the subarachnoid space.

Methods and results

Local Ethics Committee approval and informed patient consent were obtained. The efficacy of the Seldinger technique for subarachnoid and extradural insertion was studied 25 times in 18 patients (14 with a subarachnoid catheter, two with an extradural stimulation lead and nine with a small diameter fibreoptic endoscope).

With the patient in the lateral position, using the median or paramedian approach, a lumbar puncture with a Tuohy needle (Perican 16 G, B. Braun Melsungen AG, Melsungen, Germany) was performed. A commercially available vascular introduction kit (Check-Flo II Introduction Set 5 Fr, William Cook Europe A/S, Bjaeverskov, Denmark) was used for the Seldinger technique. Under fluoroscopic control a guide wire was advanced through the needle 5–10 cm into the subarachnoid space. By sliding it over the guide wire, the Tuohy needle was removed. The plastic catheter sheath with the dilator was then advanced over the guide wire. Successively the guide wire and dilator were removed. Through the sheath the spinal catheter (Implantable Spinal Catheter 8703 and 8706, Medtronic Inc., Minneapolis, USA), lead (Pisces Quad 3487A, Medtronic Inc., Minneapolis, USA) or a 1.4-mm

fibreoptic endoscope (Olympus Europe, Hamburg, Germany) could then be introduced easily.

In four cases post-spinal headaches were observed, which were treated successfully with a homologous blood patch. No other complications were observed.

Comment

This study has indicated that the Seldinger technique is an effective method of inserting an extradural catheter, lead or fibrescope into the subarachnoid space. When a Tuohy needle is used for subarachnoid cannulation, the sharp needle edges are potentially damaging. In particular, retrograde movements through the needle have to be avoided. When these movements are necessary it is strongly advised to remove the Tuohy needle together with the catheter and to repeat the lumbar puncture. This can be difficult in severely spastic patients. Furthermore, re-insertion of the rather large diameter Tuohy needle increases the risk of CSF leakage. The most important advantage of the Seldinger technique is that frequent manipulations through the plastic introducer in fibreoptic spinaloscopy and in difficult subarachnoid catheter and extradural lead insertion can now be performed without adverse effects to the apparatus.

With the modified Tuohy needle (Pisces Quad 3487A, Medtronic Inc., Minneapolis, USA) introduction of a stimulation lead in the extradural space is hampered. By using the Seldinger technique, a standard Tuohy needle is used and the extradural space can be identified easily with the loss of resistance method.

The use of the plastic sheath in the Seldinger technique is very important. It protects the fibreoptic scope during multidirectional manipulations. Introduction of a plastic sheath with its silicone membrane into the spinal space gives far superior control on CSF fluid loss. A frustrating complication of chronic spinal drug delivery systems is disconnection of the two spinal catheter parts [2]. A single piece spinal catheter with a plastic introducer sheath which may be split and removed is in the process of development.

Spinal puncture with a Tuohy needle has a high incidence of post-spinal headache [2]. The incidence of spinal headache in our patients treated with the Seldinger technique was similar to that using the classic Touhy needle spinal puncture technique. The use of a guide wire in the Seldinger technique does not differ from the original technique of introducing a spinal silicone catheter and seems therefore to be an acceptable technique.

The technique is thought to be atraumatic and hopefully may lead to a reduction in catheter morbidity in long-term use. There were no short- or long-term neurological sequelae in the patients reported here. Further studies in this area would be valuable.

Regional anaesthesia for outpatient nasal surgery

S. MOLLIEX, M. NAVEZ, D. BAYLOT, J. M. PRADES, Z. ELKHOURY AND C. AUBOYER

Summary

Regional anaesthesia is not used widely for outpatient nasal surgery. The aim of this study was to determine the role of nasociliary and infraorbital nerve block in 24 patients undergoing nasal surgery comprising: cosmetic or reconstructive surgery of the nose and surrounding soft tissue, polypal removal, turbinectomy, reduction of fractured nasal bones, small tumour resection or emergency surgery on isolated facial lacerations. Mild sedation with midazolam 0.03 mg kg^{-1} was used before anaesthesia. Nasociliary and infraorbital blocks were technically easy to perform, safe and provided good intraoperative conditions. Only minor complications were observed, including local bruising in eight patients and transient diplopia in one patient. No patient received general anaesthesia, but infiltration of local anaesthetic was necessary in four patients because of incomplete anaesthesia in the surgical area. Operative conditions were judged as good or excellent by surgeons in 20 of 24 patients. Twenty of 24 patients were very satisfied or satisfied with anaesthesia. Duration of surgery exceeding 60 min and excessive bleeding in the nasopharynx were the main limiting factors for the use of facial regional anaesthesia. (*Br. J. Anaesth.* 1996; **76**: 151–153)

Key words

Anaesthetic techniques, regional. Anaesthesia, day-case. Surgery, facial. Surgery, plastic.

Regional anaesthesia of the face is used commonly for diagnosis or neurolytic blocks for chronic pain syndromes. However, these techniques have limited use as safer general anaesthesia has developed because of the discomfort and stress produced by facial surgery. Facial surgery is very frequently performed on an outpatient basis, especially for minor procedures involving the soft tissues of the nose, cheek, lower eyelid and upper lip. Regional anaesthesia may offer several advantages for the ambulatory patient, including: avoidance of the common side effects of general anaesthesia and tracheal intubation; decrease in patient recovery time; and residual analgesia in the early postoperative period [1]. The purpose of this study was to evaluate if outpatient nasal surgery performed under regional anaesthesia was safe and not accompanied by severe discomfort.

Methods and results

After obtaining informed consent, we studied 24 patients, mean age 36 yr (range 19–62 yr). Nineteen patients were scheduled for different nasal surgical procedures including: cosmetic or reconstructive surgery of the nose and surrounding soft tissue (12), polypal removal (1), turbinectomy (2), reduction of fractured nasal bones (2) and resection of small tumours (2). Five patients with a "full stomach" were managed as emergencies for isolated nasal or upper lip lacerations, or both, after facial trauma. Regional anaesthesia was performed on each side by block of the infraorbital nerve and nasal branches of the nasociliary nerve, with patient supine.

The nasociliary nerve is a branch of the ophthalmic nerve giving off several important groups of branches while in the orbital cavity. The ethmoidal branches supply the mucous membrane of the sphenoidal, ethmoidal and frontal sinuses. The nasal branches supply the mucous membrane of the anterior part of the septum, the lateral wall of the nasal cavity, and the skin of the ala and apex of the nose by the internal and external branches, respectively [2]. To block the nasociliary nerve or its branches, a 3-cm, 25-gauge needle was inserted 1 cm above the inner canthus and directed posterolaterally, keeping contact with bone. At a depth of 1.5 cm the needle should be at the anterior ethmoidal foramen, and 2 ml of anaesthetic solution was then injected. The needle was then advanced slowly 1 cm further to reach the posterior ethmoidal foramen where 1.5 ml of solution was injected to block the posterior ethmoidal nerve that supplies the posterior sinuses. The two injections were also likely to block another branch of the nasociliary nerve, the infratrochlear nerve which supplies the root of the nose [3].

The infraorbital nerve is a terminal cutaneous branch of the maxillary nerve emerging through the infraorbital foramen. It divides into three groups of branches supplying the skin of the nose and the septum mobile nasi, the upper lip and its mucosa, and the lower eyelid and its conjunctiva [2]. To block the infraorbital nerve, an oral approach was performed as follows: the infraorbital foramen was

Correspondence to S.M.

palpated approximately 2.5 cm from the midline of the face, on an imaginary straight line passing through the supraorbital notch, the pupil of the eye, the infraorbital foramen and the second bicuspid tooth. Depression of the foramen was fixed with a finger while a 3-cm, 25-gauge needle was inserted in the mucobuccal fold along the axis of the bicuspid tooth. The needle tip was advanced, being guided by the finger over the foramen. Anaesthetic solution (3 ml) was injected in the vicinity of the foramen without entering the canal [4].

Blocks were carried out with a mixture of equal volumes of 0.25 % bupivacaine and 1 % lignocaine with adrenaline 1:400000. The nasociliary blocks were produced without adrenaline to eliminate any risk of retinal artery spasm. In addition, for surgical procedures involving the mucous membrane of the superior and middle turbinates and the posterior part of the septum, topical anaesthesia of the nasal branches of the pterygopalatine nerves was performed on each side. These branches lie on the lateral wall of the nasal passage, just posterior to the middle turbinate. A small piece of gauze soaked in a mixture of 5 % lignocaine and 0.25 % phenylephrine was introduced along the middle turbinate and placed at the end of the nasal passage for at least 10 min [3]. This combination of vasoconstrictor and anaesthetic agent reduced bleeding during surgery. The nasociliary and infraorbital nerve blocks were considered adequate in the first instance, if the apex and the skin on the side of the nose were anaesthetized, respectively. I.v. sedation was administered before anaesthesia with midazolam 0.03 mg kg^{-1}.

The following variables were assessed: time to full sensory loss in the anaesthetized area, tolerance of the surgical procedure estimated by the surgeon on a four-point scale (excellent, good, fair or poor), time to recover light touch and patient satisfaction after surgery on a four-point scale (very satisfied, satisfied, little satisfied or dissatisfied).

Sixty-seven blocks were produced, including 42 nasociliary and 25 infraorbital blocks. They were associated with topical anaesthesia of the pterygopalatine nerves in only seven patients. Depending on the surgical procedure, the number of blocks performed on each patient was 1, 2, 3 and 4 for 2, 11, 1 and 10 patients, respectively. The blocks were frequently bilateral, particularly for surgical procedures involving the nasal cavity. Mean time to full sensory loss was 11 (range 5–15) min, mean duration of surgery was 45 min (range 15–90 min), and mean duration of block before recovery of light touch sensory was 1 h 31 min (range 30 min–2 h 30 min). However, the latter result was affected by the use of lignocaine alone for the two shortest surgical procedures (15 min). No patient received general anaesthesia, but infiltration of local anaesthetics was necessary in four patients because of incomplete anaesthesia in the surgical area. Additional administration of midazolam was necessary during surgery in 11 patients without exceeding a dose of 0.05 mg kg^{-1}. The minor side effects of nasociliary blocks were: a little bruise and swelling of the upper lid in eight patients and diplopia disappearing as the block dissipated in one other patient. In our study, an intraoral approach was performed to block the infraorbital nerve. By using this approach and a 3-cm, 25-gauge needle, no haematoma was noticed. Tolerance of the surgical procedure was considered fair (2) or poor (2) in four patients compared with good (16) or excellent (4) in 20 patients. Twenty-two patients were very satisfied (10) or satisfied (12), but two patients were dissatisfied because of the feeling of suffocation from draping the face (one) and swallowing of blood (one).

Comment

The results of the present study demonstrated that regional anaesthesia is suitable for outpatient nasal surgery.

Nasociliary and infraorbital blocks are technically easy to perform, safe and provide good intraoperative conditions. These blocks also produce good anaesthesia. Indeed, nasociliary and infraorbital nerves blocks are considered adequate in the first place if the apex and side of the nose are anaesthetized, respectively. Because adrenaline is not used for the nasociliary block to prevent any risk of retinal artery spasm, this block wears off first. Thus, the mean duration of block represents the mean duration of anaesthesia in the area supplied by the nasociliary nerves. This could explain the short duration of block in our study. Consequently, we suggest that the infraorbital nerve is blocked before nasociliary block, even if the duration of anaesthesia is not increased significantly because of the short time taken to block the infraorbital nerve. The failure rate was 16 % (4/24), which is low with regard to the total number of blocks carried out (67). This rate included only partial failure allowing surgery to proceed with single local anaesthetic infiltration. In addition, in the case of unilateral surgery, a smaller number of injections is required to perform anaesthesia, and this also decreases the risk of failure.

All of the failures involved the nasal cavity. However, it is extremely difficult to be certain each time which are the appropriate blocks because the areas supplied by the nasociliary and pterygopalatine nerves overlap. The lack of pterygopalatine nerve block may be responsible for some failures reported in our study. No major complication was observed and swelling of eyelid, the more common side effect of nasociliary block, may be prevented by local pressure during anaesthetic injection. The time to prepare and perform the blocks, and the onset time are appropriate for the outpatient setting. Light sedation with midazolam allows anaesthetic and surgical procedures to be performed without severe discomfort and stress, as assessed by patient satisfaction.

The amnesic effect of midazolam may make it difficult to assess adequately "patient satisfaction". However, midazolam was used in small doses (0.03 mg kg^{-1}) to relieve anxiety just before the blocks were carried out and a dose of 0.05 mg kg^{-1} was not exceeded. We do not believe that in these doses the amnesic effects of midazolam dramatically modified patient assessment of satisfaction. However, duration of surgery exceeding 60 min and excessive bleeding in the nasopharynx are felt as unpleasant and represent the main limiting factors the use of regional anaesthesia in facial or nasal surgery.

Facial surgery may also be performed by local anaesthetic infiltration [5, 6]. However, regional nerve blocks have advantages over infiltration for facial anaesthesia because there is less tissue swelling at the operative site [5]. Some operations performed in our study could have been undertaken with simple packing of the nose with local anaesthetic agents. However, in our experience, anaesthesia produced by simple packing does not allow surgery on deep tissues without severe discomfort even if the patient is also sedated. In emergency cases, infiltration anaesthesia is satisfactory for small clean wounds of the face, but injection of local anaesthetics into or around dirty or macerated wounds, with the risk of distortion and damage of tissue, should be avoided. Furthermore, most of the patients treated as emergencies are assumed to have a full stomach, and regional anaesthesia in this context avoids the risk of general anaesthesia.

Effect of smoking on dose requirements for vecuronium

H. Teiriä, P. Rautoma and A. Yli-Hankala

Summary

We have compared the potency of vecuronium given to 12 smokers and 12 non-smokers during propofol–alfentanil–nitrous oxide anaesthesia. After obtaining individual dose–response curves, bolus doses of vecuronium were given to maintain neuromuscular block at 90–98% for 60 min. Adductor pollicis EMG was used to monitor neuromuscular block. Mean ED_{95} values were 61.38 μg kg^{-1} and 47.49 μg kg^{-1} for smokers and non-smokers, respectively ($P < 0.01$). The dose of vecuronium to maintain 90–98% neuromuscular block was 25% higher in smokers than in non-smokers (96.80 *vs* 72.11 μg kg^{-1} h^{-1}; $P < 0.01$). These data reflect the effects of smoking on neuromuscular block induced by vecuronium. The effect may be at the receptor level, although possible increased metabolism of vecuronium in smokers cannot be excluded. (*Br. J. Anaesth.* 1996; **76**: 154–155)

Key words

Neuromuscular block, vecuronium. Complications, smokers.

Smoking changes the potency of many drugs [1]. The effect of smoking on the pharmacodynamics of neuromuscular blockers is poorly understood. A recent study suggested that cigarette smokers are more sensitive to atracurium than non-smokers, possibly because of down-regulation of receptors [2]. However, our clinical impression is that smokers seem to consume more vecuronium than non-smokers. Therefore, we designed a study to evaluate the effect of smoking on the pharmacodynamics of vecuronium.

Methods and results

The study was approved by the Ethics Committee of the hospital. All patients were white, ASA I–II. Twelve smokers (six female; median age 35 (range 19–49) yr; weight 69 (55–91) kg) and 12 non-smokers (eight female; median age 41 (20–47) yr; weight 65 (59–85) kg) gave informed consent. Exclusion criteria were: body weight index more than 27; any disease or medication known to affect neuromuscular block; and weekly alcohol consumption more than 20 units (1 unit = one drink, a glass of wine or a bottle of beer). Smokers inhaled more than 10 cigarettes per day.

Patients were premedicated with midazolam 15 mg orally. An antecubital vein was cannulated for i.v. infusion. Neuromuscular function was monitored by adductor pollicis EMG (Relaxograph, Datex/Instrumentarium, Finland). The stimulating surface electrodes were placed over the ulnar nerve, the recording electrode over the adductor pollicis muscle and the reference electrode on the proximal area of the second finger. The forearm and thumb were attached to a dorsal splint to maintain immobility. The hand was covered with an aluminium sheet to prevent cooling. Skin temperature of the hand was maintained at more than 33 °C.

Anaesthesia was induced with alfentanil 10–20 μg kg^{-1} and propofol 2–3 mg kg^{-1}, and maintained with an infusion of propofol 6–10 mg kg^{-1} h^{-1}, 66% nitrous oxide in oxygen and bolus doses of alfentanil up to 50 μg kg^{-1} h^{-1}. The neuromuscular monitor was calibrated after induction of anaesthesia and before administration of the neuromuscular blocker (supramaximal train-of-four stimulation, 2 Hz every 20 s). Calibration was continued until unchanged EMG responses were recorded for more than 2 min.

After calibration, the first dose of vecuronium 20 μg kg^{-1} was given. The ensuing block was monitored until stabilization. The ED_{95} for vecuronium was calculated by creating an individual dose–response curve. For this purpose, vecuronium was given according to the two-dose technique described previously [3]. Tracheal intubation was performed when the EMG response was $< 15\%$ of baseline. Neuromuscular block was maintained at 90–98% for 60 min by administering vecuronium boluses (20% of the estimated individual ED_{95} dose) when needed. The dose of vecuronium was recorded and calculated later. Analysis of variance, followed by Scheffe's *post hoc* test, was used to compare means. $P < 0.05$ was considered statistically significant.

The results of the study are presented in table 1. The response after the last individual incremental dose of vecuronium was 95–98% of maximum and it averaged 12.1 min (no significant difference between groups). Mean end-tidal carbon dioxide concentration was 5.04% (ns). Skin temperature averaged 34.8 °C (ns).

Table 1 Mean (95% confidence limits) values of hourly consumption of vecuronium (Cons), slope of the dose–response (Slope), ED_{95} and ED_{95}/hourly consumption of vecuronium (Ratio) between smokers and non-smokers. $^{**}P < 0.01$ between groups (ANOVA and Scheffe's test).

	Smokers	Non-smokers
Cons ($\mu g\ kg^{-1}\ h^{-1}$)	96.80** (88.49, 105.10)	72.11 (64.46, 79.77)
Slope (probit $\log^{-1}$)	6.48 (5.66, 7.29)	7.33 (5.80, 8.86)
ED_{95} ($\mu g\ kg^{-1}$)	61.38** (53.27, 69.49)	47.49 (42.16, 52.82)
Ratio	1.65 (1.43, 1.87)	1.53 (1.37, 1.68)

Comment

Our study suggested that smokers are more resistant to vecuronium than non-smokers. The site of this action is not clear. Both ED_{95} values and the hourly consumption of vecuronium were increased in smokers. Increased ED_{95} values probably reflect altered pharmacodynamics at the receptor site. Increased hourly consumption of vecuronium may indicate either increased plasma concentration of the drug, i.e. increased requirement of vecuronium at the receptor site to maintain neuromuscular block, or increased metabolism. The ED_{95}/consumption ratio of vecuronium did not differ between groups, nor did the slopes of the dose–response curves. The similar slopes of the dose–response curves may indicate that the metabolism of vecuronium during construction of the dose–response curve did not differ between groups.

Small doses of nicotine (< 100 ng ml^{-1}) stimulate the neuromuscular junction directly (acetylcholine-like action) and facilitate transmission of impulses. Larger doses ($> 10\ \mu g\ ml^{-1}$) block transmission because of persistent depolarization (acute effect) or desensitization of the receptor site (chronic effect) [4]. Based on the routine procedures of our hospital, patients were not allowed to smoke for 6 h before anaesthesia. Even heavy smoking does not increase blood nicotine concentrations to more than 75 ng ml^{-1} [5]. Low blood concentrations of nicotine might, therefore, partly explain our results. Tobacco smoke, however, is a mixture of more than 3000 different compounds [1]. It has enzyme-inducing properties; enhanced biotransformation of many drugs sharing the cytochrome P-450 mixed function oxidase pathway has been correlated with cigarette smoking [1]. Therefore, factors other than directly nicotine-induced mechanisms may play a role in increased resistance of vecuronium in smokers.

We measured the ED_{95} for vecuronium over a period of 12 min. If metabolism of vecuronium were increased, this relatively long measurement time might result in inaccurately increased ED_{95} values in smokers [6]. Our measurement method was therefore not ideal. However, the difference in ED_{95} value between smokers and non-smokers was more than 20%. This probably cannot be explained solely by increased metabolism of the drug. An altered mechanism of action on the neuromuscular junction may also be involved therefore.

In the report of Kroeker, Beattie and Yang [2], smokers appeared to require less atracurium than non-smokers. This contrasts with the results presented here. More studies are needed to elucidate the mechanism of the effects of cigarette smoking on the neuromuscular junction and clarify this difference.

CASE REPORTS

Airway problems after carotid endarterectomy

F. J. MUNRO, A. P. MAKIN AND J. REID

Summary

Respiratory obstruction has been reported as a complication of carotid endarterectomy; the causes include traumatic mucosal oedema, direct tracheal compression by haematoma and oedema secondary to lymphatic and venous congestion. We report four cases of acute respiratory obstruction complicating carotid endarterectomy. Two of these cases suffered respiratory arrest in the postoperative ward and required emergency tracheal intubation in difficult circumstances. All of these patients had developed wound haematomas and all required surgical intervention. (*Br. J. Anaesth.* 1996; **76**: 156–159)

Key words

Surgery, endarterectomy. Airway, obstruction. Complications, airway obstruction.

Carotid endarterectomy is of proven efficacy in moderate to severe carotid artery stenosis [1]. Surgery involves a vascular graft and manipulation of the carotid body. Recognized complications include postoperative hyper- or hypotension, wound haemorrhage, local oedema and neurological deficits [2]. Airway obstruction is well recognized; this may be caused by haematoma formation, oedema or a combination of both [3]. During a 1-yr period in our unit when 100 procedures were performed, there were four cases of haematoma leading to a compromised airway which required acute airway management and surgical intervention.

Case reports

PATIENT NO. 1

A 71-yr-old male was admitted for left carotid endarterectomy having suffered a cerebrovascular accident 10 months previously. His past medical history included hypertension and ischaemic heart disease treated with aspirin, nifedipine and bendrofluazide. His preoperative arterial pressure was 180/90 mm Hg. The operation was uneventful. Throughout the procedure the patient had a stable cardiovascular system and an arterial cannula was used to monitor arterial pressure. According to our standard routine management, heparin 3000 u. was administered i.v. and reversed later with protamine 30 mg i.v. After operation, in the recovery unit, invasive arterial pressure monitoring was continued. Recovery was complicated by systolic hypertension which was treated with increments of hydralazine i.v., however, a systolic arterial pressure of 260 mm Hg was reached before control was achieved.

A neck haematoma was first noticed 1 h from completion of the procedure. At this time the patient's coagulation profile was normal. The haematoma continued to expand and 5 h after operation the patient was noted to be hoarse. On examination there was no respiratory distress and the trachea was central. The patient was reviewed by the vascular surgeon and the area of haematoma was marked. One hour later, with no further evidence of enlargement of the neck swelling, the patient was transferred to the postoperative surgical ward where invasive arterial pressure monitoring was discontinued. Nine hours after operation the patient became acutely dyspnoeic and developed stridor. This progressed rapidly to complete airway obstruction and respiratory arrest. At laryngoscopy no normal structures were seen, the soft tissues were grossly oedematous and friable, with fresh bleeding on pharyngeal suction. Intubation was achieved blindly with a 6.0-mm tracheal tube via the right side of the pharynx. The patient was sedated, paralysed and transferred to the operating theatre where a large haematoma was evacuated. The left facial vein was identified as the source of bleeding and was ligated. Small bleeding points were also sutured on the arterial vein patch. Before tracheal extubation was attempted a gum elastic bougie was inserted. The tracheal tube was then removed and laryngoscopy showed the larynx to be central with both vocal cords moving normally. After removal of the bougie there was no stridor.

Haemoglobin concentration decreased from 13.3 g dl^{-1} before operation to 9.9 g dl^{-1}. The patient made a full recovery and was discharged on day 5 after operation with no neurological deficit.

PATIENT NO. 2

A 72-year-old male was admitted for left carotid endarterectomy having suffered multiple transient ischaemic attacks in the preceding months. He had a

FIONA J. MUNRO, FRCA, ANDREW P. MAKIN, FFARCSI, FRCA, JOYCE REID, FRCA, Department of Anaesthesia, Western Infirmary, Dumbarton Road, Glasgow G11 6NT. Accepted for publication: August 14, 1995.

history of hypertension. His treatment consisted of aspirin, bendrofluazide, atenolol and diltiazem. Preoperative arterial pressure was 170/68 mm Hg. The operation was uneventful. Intraoperatively heparin 3000 u. i.v. was administered and reversed later with protamine 30 mg, i.v.

After operation, in the recovery unit, he developed hypertension, peaking at 220/130 mm Hg, despite early treatment with bolus doses of i.v. hydralazine. Neck swelling was first noted 30 min after operation; however, after regular surgical review in the recovery unit it was decided to pursue conservative management. With arterial pressure stable and no apparent further increase in haematoma size, the patient was transferred to the surgical ward. Here, after 8 h, the patient developed acute respiratory embarrassment leading to respiratory arrest. At laryngoscopy no anatomical structures could be identified and the trachea was intubated blind with a 7.5-mm tracheal tube through swollen mucosal folds. The patient was then transferred to the intensive care unit. On return to theatre the following morning a large haematoma was evacuated and a bleeding point on a branch of the internal jugular vein ligated. Tracheal extubation 4 h later was uneventful. His haemoglobin concentration decreased from 13 to 9.6 g dl^{-1} and required transfusion of 2 u. of packed red cells. Postoperative recovery was complicated by transient right-sided weakness and dysphasia which resolved before discharge on day 7 after operation.

PATIENT NO. 3

A 79-yr-old male was admitted for right carotid endarterectomy. He had suffered several transient ischaemic attacks in the preceding months and had a history of treated hypothyroidism. His regular medication consisted of aspirin, propranolol and thyroxine. Preoperative arterial pressure was 160/70 mm Hg. The operation was complicated by low stump occlusion pressure, difficulty in inserting the Javed shunt and oozing from the vein graft, requiring extra sutures. Heparin 3000 u. i.v. was administered and reversed later with protamine 30 mg i.v. In the recovery unit a systolic pressure of 220 mm Hg was recorded 6 h after operation which was treated promptly with i.v. hydralazine. At this time the patient was agitated, hoarse and had developed a wound haematoma. He was reviewed by the surgeon at this time and it was decided to manage the patient conservatively on the postoperative surgical ward. At 10 h after operation he had developed stridor and was therefore returned urgently to theatre.

A rapid sequence induction was performed with etomidate 8 mg, midazolam 2.5 mg and suxamethonium 100 mg. Initially at laryngoscopy no normal structures could be identified because of the grossly distended pharyngeal veins and oedematous soft tissues. On further manipulation, the larynx was seen deviated to the far left of the pharynx. Intubation was then accomplished with an 8.5-mm tracheal tube. At operation a large haematoma was evacuated and haemostasis was produced with sutures to the vein graft. After operation he was transferred to ITU and the trachea extubated uneventfully within a few hours. His preoperative haemoglobin concentration of 11.2 g dl^{-1} decreased to 7.6 g dl^{-1} after operation. His recovery was complicated by a transient hemiparesis and cerebellar signs which resolved before discharge.

PATIENT NO. 4

A 56-yr-old male was admitted for left carotid endarterectomy. He had suffered several transient ischaemic attacks in the previous 6 months and was receiving regular aspirin treatment. He had no other significant medical history. Preoperative arterial pressure was 130/80 mm Hg. At operation a Javed shunt was inserted and standard anticoagulation and reversal administered. In the recovery unit he developed systolic hypertension of 210 mm Hg which was treated successfully with sublingual nifedipine. At this time he was noted to be hoarse and had developed a neck haematoma. He remained in the recovery unit and was reviewed by the surgeon who considered surgical intervention unnecessary. Before transfer to the surgical ward, the haematoma was unchanged in appearance for longer than 1 h, with minimal drainage.

At 6 h after operation in the surgical ward, the neck swelling had progressed and it was decided to explore the wound. On assessment of the airway there was limited mouth opening as a result of gross neck swelling. An inhalation induction was performed with oxygen, nitrous oxide and enflurane. As the airway was easy to maintain, etomidate 12 mg and suxamethonium 100 mg were administered. Intubation was straightforward with a 9.0-mm tracheal tube. At operation a large haematoma was removed, a small artery was cauterized and a defect in the left facial vein sutured. Tracheal extubation immediately after operation was uneventful. His preoperative haemoglobin concentration decreased from 13.9 to 12 g dl^{-1}. He was discharged home on day 4 after operation with no neurological deficit.

Discussion

Previous reports have postulated that the aetiology of airway obstruction after carotid endarterectomy surgery may be direct tracheal compression by haematoma, oedema secondary to either direct mucosal trauma or lymphatic and venous congestion resulting from haematoma formation [4, 5]. Reports suggesting oedema as the primary causal factor have described evacuation of haematoma which did not immediately relieve the airway obstruction; indeed 10 h of elective ventilation after operation has been recommended [6]. Dexamethasone has also been recommended prophylactically after prolonged neck surgery for this reason [7]. However, evacuation of haematoma has also been reported to relieve airway obstruction immediately [8].

Among the four cases described here, there were striking similarities in the perioperative events, which may have contributed to the development of similar postoperative complications. All patients were receiving aspirin as antiplatelet therapy which theoretically may have resulted in impaired clot formation, aggravating any bleeding. Also, they all received i.v. anticoagulation during operation, although this was reversed adequately with i.v. protamine.

Despite continuous arterial pressure monitoring and the presence of a recovery anaesthetist, postoperative hypertension was common to all cases in the first 6 h. This was controlled successfully with either hydralazine or nifedipine and may have contributed to arterial bleeding but would not account for haematoma formation caused by venous bleeding. Hypertension is well recognized after carotid endarterectomy; it may be caused by carotid body stimulation, pain or neurological insult. Urgent treatment of such severe hypertension is imperative in order to avoid cerebral haemorrhage. When using i.v. vasodilator therapy the dose must be titrated to effect in order to avoid myocardial or neurological damage caused by inadvertent hypotension.

In all cases, the neck haematomas were large and associated with a decrease in haemoglobin (1.9–3.6 g dl^{-1}). All patients were reviewed by vascular surgeons who, in the absence of airway difficulties and no further neck swelling, considered surgical intervention inappropriate.

Of these patients, three subsequently developed hoarseness but only in one case was evacuation of the haematoma carried out when minimal airway distress was present. In the other two cases conservative management continued until surgery was prompted by respiratory arrest when gross anatomical distortion was found at laryngoscopy. At exploration definite venous bleeding points were identified in three cases; two of these were also bleeding from the arterial vein patch.

It is of interest that in the four cases presented, in two the trachea was extubated at the end of the procedure and in one at 4 h after operation without complications. The fourth was transferred to the regional intensive care unit where evacuation of haematoma was scheduled for the next day and the trachea was extubated 4 h after operation.

Of the three mechanisms of airway obstruction described above, we suggest that haematoma causing lymphatic and venous congestion leading finally to oedema was the most likely sequence of events. This is supported by the delayed onset of airway obstruction and the rapid resolution of oedema after evacuation of the haematoma facilitating early tracheal extubation after operation.

In the emergency situation the airway may be difficult to assess and the degree of expected difficulty is often not fully appreciated. The final life-threatening deterioration is frequently rapid with little warning. Stridor appears to present late as a clinical sign. However, subtle changes in voice quality progressing to hoarseness in the presence of such acute neck swelling should be treated as an indication of impending airway obstruction. In the above cases developing haematoma was initially managed conservatively (6–10 h) before intervention. It is of concern that two of these patients suffered respiratory arrest and in both the trachea was intubated blindly on the ward under difficult conditions.

In order to avoid the catastrophic consequences of respiratory arrest from a completely obstructed airway we suggest that progressive neck swelling should be managed aggressively with early surgical intervention. Successful evacuation of such haematomas under local anaesthesia has been reported. Also, after extensive neck surgery patients should be managed in a high dependency unit with appropriate monitoring, levels of nursing staff and the immediate availability of anaesthetic expertise.

In the event of airway obstruction, management strategies that have been documented include inhalation induction, with or without helium, to decrease turbulent airflow. Fibreoptic intubation has also been advocated, although this technique required a skilled operator and vision may be impaired by anatomical distortion, venous congestion and secretions. Also, the smallest tracheal tube accommodated by the standard intubating bronchoscope is 6.5 mm which may be difficult to pass. Both the retrograde intubation technique and the creation of a surgical airway may be difficult and extremely dangerous in the swollen neck.

It is of concern that anaesthesia was induced in one patient with a rapid sequence induction resulting in unexpected difficulty in seeing the larynx. Fortunately, there were no long-term sequelae as a result of this delay in securing the airway. However, in a previous report of six similar cases, four of which were initially paralysed resulting in inability to ventilate the lungs, all suffered severe hypoxia and cardiac arrhythmias [4]. In three of these the trachea was intubated with difficulty using small tracheal tubes and one underwent emergency tracheostomy while asystolic.

The appropriate moment for extubation may be difficult to assess. From our experience it would seem that elective postoperative ventilation is not always necessary. Various methods may assist in assessing the ability to extubate the trachea successfully at the end of the procedure, namely an audible leak around the deflated cuff at 15 cm H_2O of airway pressure or leaving a gum elastic bougie or a Cooke airway exchanger *in situ* after removal of the tracheal tube.

All patients recovering from carotid endarterectomy require high dependency care to ensure continuous assessment of respiratory and cardiovascular systems. In our unit there is a planned upgrading of the postoperative surgical ward to high dependency status.

Mivacurium chloride and late onset congenital myopathy

M. PARMAR AND R. P. F. SCOTT

Summary

We describe the successful use of the short-acting, non-depolarizing neuromuscular blocking agent, mivacurium, in a 53-yr-old female patient with late onset congenital myopathy, undergoing elective submucous resection of the inferior turbinates. She was unable to climb stairs and walking was limited to periods of 15 min because of generalized weakness, fatigue and shortness of breath. A Datex Relaxograph was used to monitor the train-of-four count. No increase in sensitivity to mivacurium was demonstrated. A dose of 12 mg (three times the recommended ED_{95}) resulted in 88% reduction of the first of the train-of-four count (T1) compared with control (TC). Spontaneous recovery of T1/TC to 100% took 11 min 20 s from the time maximum block was first achieved. The recovery index (25–75% T1/TC) was 4 min 40 s. (*Br. J. Anaesth.* 1996; **76**: 160–162)

Key words

Neuromuscular block, mivacurium. Complications, myopathy.

Abnormal responses to neuromuscular block are well recognized in several muscle disorders [1–4]. Late onset congenital myopathy presents in adulthood with a gradual generalized weakness of not only the limb muscles but also the respiratory muscles. Little is known about the effect of neuromuscular block in patients with congenital myopathy. The few cases that are reported describe the use, without complications, of normal doses of the long-acting neuromuscular blocking agent, pancuronium, in patients who presented in childhood with this condition [5, 6]. We are unaware of any previously reported use of the short acting neuromuscular blocking drug, mivacurium, in patients with adult onset congenital myopathy.

Case report

MEDICAL HISTORY

A 53-yr-old female patient, weighing 50 kg, height 177 cm, presented for elective submucous resection of the inferior turbinates. She had a long history of muscle weakness dating back to adolescence when she found that she had difficulty keeping her arms above her head for any period of time. In her late twenties she had difficulty climbing stairs and more recently was unable to do so. She used crutches to walk but was limited to periods of 15 min because of generalized weakness, fatigue and shortness of breath. She wore a neck collar continuously as the weakness in her neck caused her head to droop. There was no specific difficulty with swallowing and no diplopia. She had no muscle weakness during childhood.

Her other past medical history revealed that she had developed osteoporosis in her forties and had been receiving hormone replacement therapy. She also suffered from dyspepsia for which she received omeprazole and cisapride. There was no family history of muscle disorders and she was a non-smoker.

CLINICAL EXAMINATION

She was a thin lady with no signs of cardiac or respiratory failure. There was wasting of the deltoid, glutei and to a lesser extent the quadriceps muscles. She was unable to abduct her arms beyond 90° offering only mild resistance to forced adduction. There was mild weakness of hip flexion and leg extension such that movement against gravity and mild resistance to force were possible but not sustained. Reflexes were symmetrical with a negative plantar reflex. Cranial nerve examination was normal.

INVESTIGATIONS

Full blood count, urea, creatinine and other electrolyte concentrations were normal, including serum creatine kinase. Electrocardiography and chest x-ray were normal. Lung function tests performed before operation showed a peak expiratory flow rate of 380 litre min^{-1} (80% of predicted). Forced vital capacity (FVC) was 1.88 litre (52% of predicted). FEV_1 was 1.85 litre (60% of predicted) with FEV_1/FVC 98%. Maximal pressures generated at the mouth, after full inspiration and full expiration, that is maximal expiratory and maximal inspiratory pressures, were measured using a mouth pressure meter (Precision Medical, Pickering, Yorks, UK). These were 26% and 36% of predicted, respectively, reflecting global respiratory muscle weakness. Carbon monoxide transfer tests were within normal limits. Nerve conduction studies were normal and a previous electromyograph showed myopathic changes. A

quadriceps muscle biopsy showed generalized widespread mild degenerative changes with selective type 2B fibre atrophy and a predominance of type 1 fibres. These changes were indicative of a non-specific congenital myopathy.

ANAESTHESIA

We were concerned that the patient would experience difficulty in breathing and prove to be a weaning problem after operation as a consequence of her generalized respiratory muscle weakness. Initial anaesthetic management therefore included pre-operative chest physiotherapy and breathing exercises and we ensured the availability of an intensive care bed.

Anaesthesia was induced with propofol 2 mg kg^{-1} and fentanyl 1 μg kg^{-1}. Anaesthesia was maintained initially with incremental doses of propofol with 66 % nitrous oxide in 34 % oxygen and the patient's breathing was assisted with a face mask at this stage.

Monitoring comprised electrocardiography, non-invasive arterial pressure, pulse oximetry, capnography and vapour analysis. The skin over the non-dominant forearm and hand was degreased using an alcoholic solution. Five silver–silver chloride electrodes were placed: two over the ulnar nerve, one over the mid-point of the distal skin crease at the wrist, one over the palmar aspect of the head of the first metacarpal and one over the belly of the adductor pollicis muscle. These were connected to a Datex Relaxograph. Neuromuscular monitoring was commenced using train-of-four (TOF) stimuli (2 Hz at 20-s intervals) to the ulnar nerve and the gated, rectified and integrated electromyograph from the adductor pollicis was recorded. A normal TOF trace was obtained. The size of the gain setting, supramaximal stimulus and the stimulus artefact were noted.

As the patient had muscle weakness, only a small dose (1 × ED_{95}) of mivacurium was administered. No effect on the TOF was seen after 4 min and therefore an additional dose of 4 mg was given. This resulted in a gradual reduction in the first twitch of the TOF (T1) which stabilized to a T1 response of 50 % compared with control (TC). Intubation was attempted with a cuffed tracheal tube size 8 mm at this stage but was unsuccessful because of difficulty in seeing the vocal cords. Another dose of mivacurium 4 mg was therefore administered 8 min after the first dose, which resulted in a decrease in T1/TC to 12 %. At this point the intubating conditions were much improved and the trachea was intubated. Maximum block of 88 % was achieved 12 min after the first dose of mivacurium had been given. The patient was taken into theatre and her lungs ventilated with 66 % nitrous oxide and 0.5 % enflurane in oxygen.

The cardiovascular system was stable and she remained normothermic throughout surgery. Additional mivacurium was not required and neuromuscular block was allowed to recover spontaneously. Recovery of T1/TC to 100 % took 11 min 20 s from the time maximum block was first achieved, with a recovery index (25–75 % T1/TC) of 4 min 40 s. Antagonism of neuromuscular block was not deemed necessary as the TOF ratio had recovered spontaneously to 1.0. The patient emerged from anaesthesia breathing spontaneously and the trachea was extubated uneventfully. Before extubation, the patient demonstrated good hand grip strength. In view of her myopathy, head lift testing was inappropriate. The postoperative period was unremarkable.

Discussion

The congenital myopathies are a rare and complex group of inherited muscle disorders which are associated with enzyme defects and structural abnormalities in the muscle fibres. Mitochondrial oxidative enzyme activity is reduced or absent in central core and multicore congenital myopathies [7–9]. The presence of abnormal muscle cell organelles such as rods and nemaline bodies characterize nemaline myopathy while abnormal nuclei are found in centronuclear myopathy [10]. In addition to the enzyme defects there is also heterogeneity of muscle fibre sizes, and atrophy or predominance of certain muscle fibres. In some patients it may be difficult to assign a specific diagnostic group as the muscle biopsy exhibits only non-specific changes and it must be noted that the cytoarchitectural changes and clinical severity may not correlate.

Most patients with congenital myopathy present in childhood. Generalized hypotonia may be detected as early as the neonatal period and delayed motor milestones are common. The child thus has difficulty in getting up from the floor, walking and later running and climbing stairs. There may be associated skeletal abnormalities such as scoliosis, pes cavus, clubbed feet or congenital hip dislocation [11]. Most cases are non or very slowly progressive; indeed, there may be early improvement in childhood but with varying degrees of subsequent deterioration [12]. The involvement of the respiratory muscles may cause respiratory failure which represents a common cause of death [5, 13].

Late onset congenital myopathies present in adulthood with gradual onset of mild muscle weakness involving proximal or distal muscle groups but eventually becoming generalized [14, 15]. As with the childhood disease, they are generally non or very slowly progressive and respiratory muscle paresis causing respiratory failure may be a contributory factor to death [16].

Our patient had a slow, progressive, disabling condition for which there was objective evidence of generalized muscle weakness. Of particular concern was the global respiratory muscle weakness, as suggested by assessment of peak inspiratory and peak expiratory mouth pressures. Failure to ventilate adequately and cough in the postoperative period may cause sputum retention and areas of lung collapse. Infection and hypoxia may supervene causing prolonged recovery and possibly even death. Fortunately our patient suffered none of these complications.

There is a predisposition to malignant hyperthermia during general anaesthesia in patients with central core congenital myopathy, particularly if associated with a raised creatine kinase concentration [17]. Muscle biopsy showed none of the features diagnostic of this type of congenital myopathy and our patient did not have a raised serum creatine kinase concentration. We therefore felt justified at the time in using a volatile agent. The importance of excluding risk factors must however be stressed before using known triggering agents of malignant hyperpyrexia in patients with muscle weakness.

Mivacurium chloride is a bis-benzylisoquinolonium diester neuromuscular blocking drug. It was selected because of its relative short duration of action. This characteristic seemed desirable as there was concern that this patient may exhibit particular sensitivity to neuromuscular block. After a single dose of $1 \times ED_{95}$, a greater than 90 % reduction in T1 compared with TC would be expected after 4 min [18]. Satisfactory intubating conditions, however, were not achieved in our patient until a total of $3 \times ED_{95}$ had been administered over 12 min. Recovery to 95 % T1/TC would be expected to take 30 min, with a recovery index of 7 min after a single bolus dose of $3 \times ED_{95}$ [18]. In our patient, recovery of T1/TC to 100 % took 23 min 20 s from the end of the first dose with a recovery index of 4 min 40 s. No unusual sensitivity to neuromuscular block with mivacurium was therefore demonstrated in our patient. Indeed, it could be argued that the patient showed some resistance to block but as the drug was given cumulatively it is more likely that some hydrolysis of the agent had occurred between increments.

Patients with neuromuscular disorders have a very variable response to neuromuscular blocking drugs. It is thus important to monitor neuromuscular function accurately in all such patients. We have described the safe and satisfactory use of mivacurium chloride in a patient with late onset congenital myopathy. However, we cannot on the basis of one patient suggest that all similar cases will necessarily have no complications, nor can we advocate an advantage in the use of mivacurium compared with other intermediate neuromuscular blocking agents.

Anaesthesia and juvenile hyaline fibromatosis

B. NORMAN, N. SONI AND N. MADDEN

Summary

Juvenile hyaline fibromatosis is a rare autosomal recessive disease characterized by large cutaneous nodules, especially around the head and neck and often involving the lips. The effects become increasingly severe with age and also include joint contractures, gingival hypertrophy and osteolytic lesions. We describe the anaesthetic management of two sisters with this disease. Safe maintenance of a patent airway is the principal anaesthetic challenge. (*Br. J. Anaesth.* 1996, **76**: 163–166)

Key words

Anaesthesia, paediatric. Complications, juvenile hyaline fibromatosis.

Two sisters with juvenile hyaline fibromatosis (JHF) presented for surgery several times at our hospital. The older sister had received her first anaesthetic at 14 months of age and subsequently had three further anaesthetics. On each occasion management of the airway had become more difficult. The younger sister had received one anaesthetic at 2 yr of age when tracheal intubation was relatively easy.

For both sisters other aspects of anaesthesia and postoperative care were straightforward. For each anaesthetic they were premedicated with EMLA cream and atropine 20 μg kg^{-1} i.m. Despite the presence of joint contractures, venous cannulation was performed successfully. When the airway was secured, the lungs were easy to ventilate with normal airway pressures and oxygenation. With the exception of the elder sister's second anaesthetic, when surgery was of short duration and a laryngeal mask was used, the sisters were given atracurium 0.5 mg kg^{-1} i.v. and the lungs ventilated. The patients remained in a stable cardiovascular state during anaesthesia. After anaesthesia the trachea was extubated with the patients awake without difficulty and they required only mild postoperative analgesia.

Case reports

PATIENT NO. 1

The older sister had her first anaesthetic at 14 months of age to enable tissue biopsies to be performed. At that age she already had very abnormal facies with polyploid masses around the mouth and limited mouth opening. She also had large irregular growths on her head and back so that padding with soft packing material was required to position her for anaesthesia and surgery. Anaesthesia was induced with oxygen and halothane, and suxamethonium 1 mg kg^{-1} was given i.v. and her trachea intubated without difficulty. Her subsequent anaesthetic was uneventful.

At 20 months of age she presented for further tissue biopsies. Anaesthesia was induced with oxygen and halothane and maintained with spontaneous breathing. Laryngoscopy was performed under deep halothane anaesthesia to assess the difficulty of intubation. It was impossible to view the epiglottis as the jaw, tongue and pharynx were infiltrated and rigid. A size 2 laryngeal mask was inserted with some difficulty; the mouth opened sufficiently to admit the mask but it took several attempts to pass it downwards behind the tongue. After insertion the laryngeal mask was used to maintain the airway with spontaneous ventilation for the remainder of the anaesthetic.

At 3 years 3 months she presented for removal of lesions around her mouth and trimming of deposits on the trunk which were beginning to ulcerate. On examination she had a grossly abnormal face with marked protuberance of her maxilla caused by infiltrations (fig. 1). Her mouth was open and would admit one finger but the tissues in and around the mouth were rigid. Her lower jaw was hard with infiltrations. She had a good air flow through her right nostril. Anaesthesia was induced with oxygen and halothane. A size 3.0-mm tracheal tube was introduced gently into the right nostril and used as a nasal airway to maintain inhalation anaesthesia while examination with a fibreoptic intubating bronchoscope was performed via the left nostril. The left nasal passage was grossly abnormal and very narrow, with hyaline deposits throughout. The epiglottis was infiltrated and looked abnormal, as did the larynx which was narrowed. It was impossible to identify the arytenoids. Intubation was performed successfully by passing a 4.0-mm tracheal tube over the fibreoptic bronchoscope.

Five months later she again presented for anaesthesia for surgical treatment of sacral ulceration and extensive debridement of facial and mouth lesions. A computed tomography scan of the airway was obtained before operation and showed significant narrowing of the pharynx and trachea (figs 2, 3). The same anaesthetic technique was used as in the previous anaesthetic. The airway viewed with the

At 3 years 3 months she presented for removal of lesions around her mouth and trimming of deposits on the trunk which were beginning to ulcerate. On examination she had a grossly abnormal face with marked protuberance of her maxilla caused by infiltrations (fig. 1). Her mouth was open and would admit one finger but the tissues in and around the mouth were rigid. Her lower jaw was hard with infiltrations. She had a good air flow through her right nostril. Anaesthesia was induced with oxygen and halothane. A size 3.0-mm tracheal tube was introduced gently into the right nostril and used as a nasal airway to maintain inhalation anaesthesia while examination with a fibreoptic intubating bronchoscope was performed via the left nostril. The left nasal passage was grossly abnormal and very narrow, with hyaline deposits throughout. The epiglottis was infiltrated and looked abnormal, as did the larynx which was narrowed. It was impossible to identify the arytenoids. Intubation was performed successfully by passing a 4.0-mm tracheal tube over the fibreoptic bronchoscope.

Five months later she again presented for anaesthesia for surgical treatment of sacral ulceration and extensive debridement of facial and mouth lesions. A computed tomography scan of the airway was obtained before operation and showed significant narrowing of the pharynx and trachea (figs 2, 3). The same anaesthetic technique was used as in the previous anaesthetic. The airway viewed with the

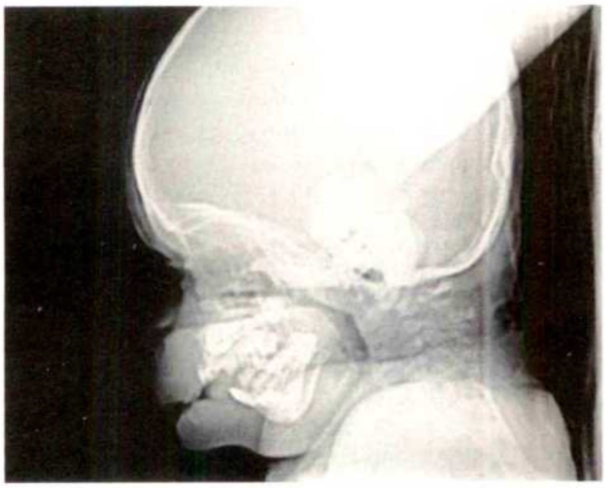

Figure 1 Lateral skull x-ray demonstrating marked soft tissue deposits adjacent to the mouth caused by juvenile hyaline fibromatosis.

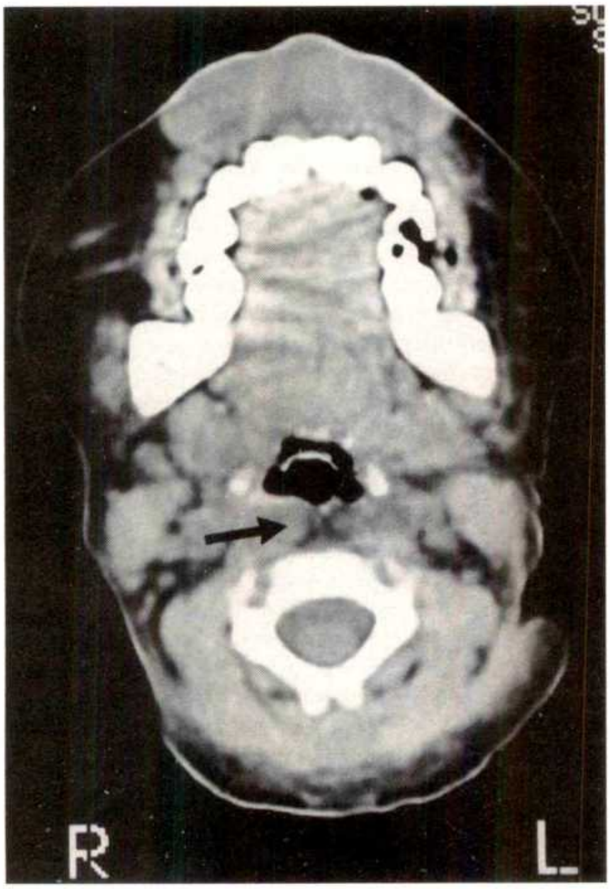

Figure 2 Computed tomography of the neck demonstrating narrowing of the pharynx. The thickening of soft tissues between the posterior pharyngeal wall and the cervical spine is marked by an arrow.

fibreoptic bronchoscope was much narrower and more tortuous than on the previous occasion. However, it did lead directly to the larynx. This was identified as a small black orifice which appeared and disappeared with breathing. There were no identifiable anatomical landmarks as these were obscured by hyaline deposits. It was clear that there had been significant progression of the infiltration since the last anaesthetic. As previously, intubation was achieved by passing a 4.0-mm tracheal tube over the fibreoptic bronchoscope.

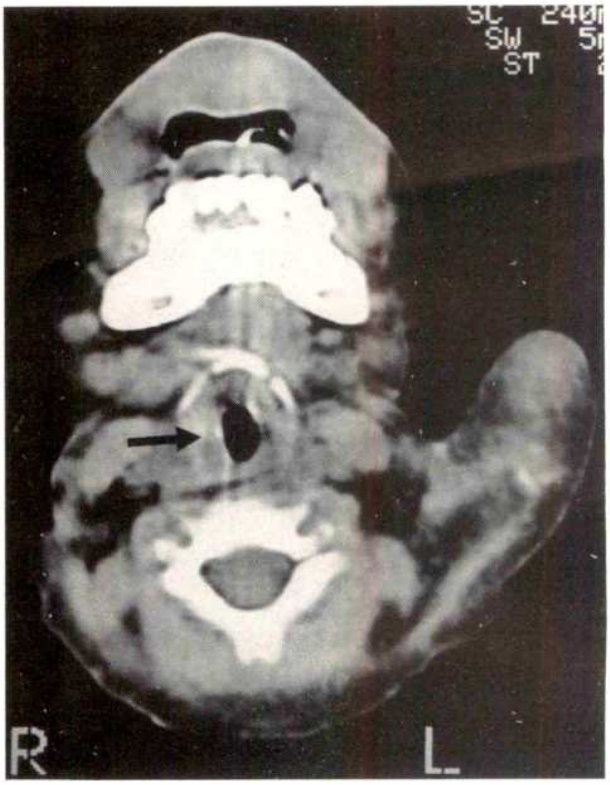

Figure 3 Computed tomography of the neck demonstrating deformation of the right lateral wall of the trachea caused by a hyaline deposit which is marked by an arrow.

PATIENT NO. 2

The younger sister presented for anaesthesia at 2 yr of age for surgical removal of lesions around the mouth. Although she had obvious facial evidence of hyaline deposits she had reasonable mouth opening. A potentially difficult intubation was anticipated as there was no indication of whether or not there might be deposits in and around the pharynx and larynx. Anaesthesia was induced with oxygen and halothane, and laryngoscopy was performed under deep inhalation anaesthesia. The lower jaw was stiff and heavily infiltrated. A straight blade enabled a view of the arytenoids but not the cords. The pharynx appeared normal. A size 3.0-mm oral tracheal tube was passed easily. Fibreoptic review of her nasal passages revealed no abnormality and a 3.0-mm nasal tracheal tube was passed while the oral tracheal tube was removed, so facilitating surgical access.

Discussion

A variety of names have been given to JHF which was first described by Murray in 1873 as "peculiar cases of molluscum fibrosum" [1]. Other names include puretic syndrome, disseminated painful fibromatosis and fibromatosis hyalinica multiplex juvenilis [2]. Infantile systemic hyalinosis is a similar condition but has an earlier onset [3].

JHF is a rare autosomal recessive disorder with variable penetrance. One-third of affected children are siblings and are often born to consanguineous marriages [2]. Clinical features develop in the first few years of life and include: multiple large slow growing cutaneous nodules on the head and neck, which involve the lips and are also found elsewhere on the body, joint contractures, gingival hypertrophy and osteolytic lesions [4–6]. Intellect is often normal [2]. Infiltration of areas such as around the mandible have, as in the two children described here, led to hard unyielding tissues with limited mouth opening. Histologically the lesions consist of an eosinophilic hyaline matrix surrounding well differentiated fibroblasts [4,5]. Previously described postmortem findings in the related disease infantile systemic hyalinosis include hyaline deposits in the skin, trachea, throughout the gastrointestinal tract, the heart, lungs, skeletal muscle, thyroid and adrenal glands [7]. Death, which occurs in the first few decades of life, may be caused by infection and there is predisposition to staphylococcal infection of skin lesions [2,3].

There have been two previous reports of anaesthetic management of JHF. Sugahara and colleagues [8] reported a 6-yr-old with JHF whose trachea was intubated successfully. Vaughn and colleagues [9] reported a 13-month-old child with JHF whose trachea was intubated with the aid of a guide wire passed through the suction port of a fibreoptic bronchoscope. Subsequent laryngoscopy revealed the epiglottis and posterior arytenoids; however, difficulty was noted in seeing the vocal cords.

Our case reports illustrate not only the airway difficulties that may be encountered with this disease, but also that as the disease progresses these are likely to become more difficult in subsequent anaesthetics. This is also the case in other diseases which are characterized by accumulation of abnormal material in the tissues. These diseases include the mucopolysaccharidoses such as Hurler's syndrome [10].

Preoperative assessment of our patients included a search for any co-existing disease but systemic manifestations resulting from hyaline deposits in organs such as the heart, lung and kidney were not present. A computed tomography scan of the pharynx was found to be useful in predicting a difficult airway.

A variety of techniques were used in the anaesthetics reported here, both as the elder sister's disease developed and as experience was gained in anaesthetic management of JHF. In all instances gaseous induction was used as it was considered the safest method to achieve induction while the airway was unsecured.

For the elder sister's first anaesthetic, suxamethonium was used for intubation because its rapid onset allowed the airway to be secured quickly. Its rapid offset would have been useful if neither intubating nor ventilating the patient's lungs with a face mask had proved possible during paralysis. However, it was not found to be necessary to use suxamethonium in any subsequent anaesthetic. Atracurium and positive pressure ventilation were used to avoid hypoventilation. Atracurium was used also in subsequent anaesthetics for the same reason. The one exception was the elder sister's second anaesthetic. In this anaesthetic laryngoscopy was attempted to assess the difficulty of intubation. When laryngoscopy proved impossible a laryngeal mask was used with spontaneous ventilation because the surgical procedure planned was short (approximately 20 min) and did not involve the mouth or face. Spontaneous ventilation was adequate for this period of time.

For the elder sister's third and fourth anaesthetics it was planned to use an intubating fibreoptic bronchoscope from the outset; laryngoscopy in the previous anaesthetic had proved impossible and use of a laryngeal mask was precluded because surgery on the mouth was planned. Under these circumstances the fibreoptic bronchoscope, used while a nasal airway allowed spontaneous ventilation, was found to be invaluable for intubation. For the younger sister's anaesthetic, intubation using laryngoscopy was achieved although the fibreoptic bronchoscope was still used to examine the airway.

Although the fibreoptic intubating bronchoscope was useful to view the airway and to secure it by facilitating intubation, there are limitations to its use. With young children, such as our patients, it is not practical to use it for an awake intubation because of the distress caused. It cannot be used for railroading a tracheal tube into the trachea if the internal diameter of the tracheal tube required is less than the diameter of the bronchoscope available, although using a guide wire passed down the suction port is an option [9]. In addition, the fibreoptic bronchoscope needs to be used by an anaesthetist experienced in its use.

Alternatives to using a fibreoptic brochoscope would have included blind nasal intubation and a bougie inserted down a laryngeal mask. However, blind nasal intubation may cause bleeding, especially in an abnormal airway, while intubating using a fibreoptic brochoscope caused no identifiable haemorrhage in the cases described here. Although no attempt was made to pass a laryngeal mask in the elder sister's last two anaesthetics, it is likely, in view of the findings with the fibreoptic bronchoscope, that a laryngeal mask would have been impossible to insert because of infiltrations in the airway.

Postoperative care was uneventful in the cases described and pain was controlled with mild analgesics. However, there is probably an increased risk of postoperative airway obstruction in patients with JHF and this may be enhanced if postoperative analgesia is required.

In conclusion, JHF, in common with other diseases associated with accumulation of abnormal material in the soft tissues, may cause increasingly severe airway problems with age. Anticipating and preparing for a difficult airway is probably more important than using any particular anaesthetic technique. However, it is recommended that the facilities for fibreoptic intubation and an experienced paediatric anaesthetist are present for all such cases.

CORRESPONDENCE

Visceral pain during Caesarean section

Sir,—In their article on visceral pain during Caesarean section, Hirabayashi and colleagues [1] stated that "The spread of analgesia in all patients was almost comparable". However, although the upper limit of spread of spinal amethocaine was measured, no attempt was made to define the lower limit of spread. Exteriorization of the uterus may lead to traction on the pelvic viscera, and pain in this region can be conveyed via the pelvic splanchnic nerves (S2, 3, 4 nerve roots) [2]. A more extensive block in the sacral nerve roots, when using higher doses of spinal amethocaine, is a possible explanation for the differences in quality of intraoperative conditions found in their study.

When presenting their data on the maximum spread of analgesia, the authors quoted a range for the upper level of the block which included non-integer values. I fail to see how they can be so accurate, especially when the dermatomal nerve supply varies between subjects and, in fact, the dermatomal chart differs immensely in description among medical books [2, 3].

3. Kumar PJ, Clark ML. *Clinical Medicine*, 2nd Edn. London: Baillière Tindall, 1990.

Sir,—We took no account of the lower limit of spread of spinal amethocaine and our conclusion was indeed derived from the data on the upper limit of analgesia. Although we had no opportunity to examine if the second, third and fourth sacral nerves were blocked during operation, none of our parturients had any sensation in the perineum during and immediately after operation, indicating that these sacral nerves were totally blocked. In contrast with extradural anaesthesia, spinal amethocaine injected at the midlumbar region usually blocks every sacral nerve. From this, we can surmise that there were no differences in the extent of block of the sacral nerves in the parturients.

Visceral pain may be transmitted via pathways as high as the coeliac plexus [1]. The coeliac plexus receives its primary innervation from the greater, lesser and least splanchnic nerves, which arise from T5 to T12 [2]. Hyperbaric anaesthetic solutions, migrating cephalad, pool in the thoracic hollow [3]. A more potent block in this region, when using higher doses of spinal amethocaine, may be a possible reason for the differences in the incidence of visceral pain found in our study.

In our article, data on maximum spread of analgesia were presented as median with range, because data on dermatomal spread are non-parametric. We assessed the spread of analgesia in the left and right sides of the body according to a dermatomal chart given in a standard textbook of neural block [4]. We believe that this female dermatomal chart is one of the most reliable for obstetric and gynaecological patients. If the analgesic levels obtained in both sides differed, the average value was used for analysis, and therefore non-integer values were provided.

Cannabis as a medicine

Sir,—We read with great interest the editorial by Doyle and Spence [1]. This was a step in the right direction and provides a concise presentation of the more recent research and concepts on the therapeutic potential of *Cannabis sativa.*

The Departments of Pharmacology and Ophthalmology of the University of the West Indies at the Mona Campus in Kingston, Jamaica have performed extensive research with *Cannabis sativa*, focusing on its possible therapeutic potential. Of course we would not advocate smoking cannabis as this could lead to some of the adverse effects described [1]. On the other hand, with regard to the gestational effects, in a long-term study in Jamaica by Dr Milaine Dreher from the University of Massachusetts and Dr Ronald Lampart in Morant Bay, Jamaica, no unusual fetal effects or growth retardation were observed. This study included mothers in early pregnancy, smoking *Cannabis sativa* through pregnancy and delivery, and their offspring were followed-up for 5 years.

Furthermore, with regard to mortality, intensive search of the literature has, to our knowledge, reported no deaths from cannabis *per se*, although the CNS effects may result in "fatalities" of one type or another.

In support of cannabis as a medicine, West and Lockhart [2, 3] from the University of the West Indies have developed an ethical preparation, an eye drop for topical administration of *Cannabis sativa*. This preparation has been marketed since 1987 and several thousand 5-cc phials have been used in some parts of the world in the management of glaucoma, particularly in the Caribbean region and some parts of North America. The drug is marketed under the tradename Canasol eye drops. In Jamaica it is manufactured by Ampec Chemicals Limited and marketed by Medigrace Limited, Kingston. Canasol is comparable with timolol maleate and is compatible with the commonly used anti-glaucoma medication. The use of Canasol eye drops has also been reported by Gutierrez and Gutierrez [4].

We agree entirely that further research is required into the use of *Cannabis sativa* or its derivatives as an analgesic and antiemetic in the postoperative period and also in the hospice setting. Even if it were to be shown that cannabis is no more useful than existing drugs, it remains a significantly cheaper and more accessible alternative in those developing countries where the newer preparations marketed by the large multinational pharmaceutical companies are unaffordable and unavailable to the general population.

Naproxen after day-case laparoscopic sterilization

Sir,—The recent article by Dunn, Clark and Jones [1] on the analgesic efficacy of a single preoperative dose of naproxen in patients undergoing day-case laparoscopic tubal ligation yet again demonstrates that pain after this procedure can rarely be treated by non-steroidal anti-inflammatory drugs (NSAID) alone. There is no doubt that pain is a very significant factor in the morbidity after laparoscopic tubal ligation [2–4]. On repeated occasions, previously published work has shown NSAID to be only partially successful in treating this pain when administered as the sole analgesic [2, 5–8].

Although there is evidence that prostaglandins mediate the pain associated with tubal ligation [9], it seems, as observed by Dunn, Clark and Jones, that this particular pain is multimodal in origin with subphrenic and shoulder tip pain originating from the persistence of irritating intraperitoneal insufflating gas [10] and cephalad tracking of blood or free fluid from the operative site via the paracolic gutters [11], and pelvic pain originating from the use of rings, clips or diathermy to occlude or interrupt the Fallopian tubes [10]. It is therefore not surprising that administration of NSAID as the lone therapeutic manoeuvre to treat this pain has proved unsuccessful. It is surely more sensible to consider NSAID as an integral component of "balanced analgesia" under such circumstances as opposed to the sole analgesic agent. It is probable that there is a proportion of patients undergoing laparoscopic tubal ligation whose postoperative pain will necessitate administration of opioid analgesia and who may, indeed, go on to require overnight hospital admission.

Sir,—As Dr Williams correctly points out, it would be inappropriate to treat the pain of laparoscopic tubal ligation with NSAID alone because of the multimodal nature of the pain. We therefore added NSAID to our normal practice of giving i.v. diamorphine during operation to extend the number of pain mechanisms being targeted. Before this study our patients commonly required additional diamorphine for postoperative pain relief, with its increased risks of nausea, vomiting and sedation, and subsequent increased likelihood of overnight stay. Our bimodal approach, using diamorphine and naproxen, decreased the need for extra postoperative diamorphine (naproxen group 21:37 = 54%; placebo group 27:35 = 77%). However, our conclusion was that a trimodal approach was required, which included a third component, local anaesthesia.

Systolic pressure variation—a way to recognize dynamic hyperinflation

Sir,—I read with interest the article by Myles, Madder and Morgan [1], the similar case presented by Mercer [2], and the reply of Myles [3], concerning cardiac arrest after unrecognized dynamic hyperinflation. The potential fatality of dynamic hyperinflation often stems from lack of recognition. I would therefore suggest that analysing the respiratory variations in the arterial pressure waveform may serve as an early warning sign of such hyperinflation. The arterial pressure waveform responds normally in a biphasic manner to a mechanical breath [4]. This response starts with an early increase in systolic pressure, termed by us delta up (dUp), which denotes transient augmentation of left ventricular (LV) stroke output caused mainly by squeezing down of pulmonary blood into the LV. The dUp is followed normally by a decrease in systolic pressure, termed delta down (dDown), which is caused by the inspiratory decrease in venous return. The difference between maximal and minimal systolic pressures during one mechanical breath is termed the systolic pressure variation (SPV) [4]. SPV and dDown (the difference between systolic pressure during a short apnoea and the minimal systolic value) are sensitive indicators of reduction in preload [4–7]. A build up of positive intrathoracic pressure during dynamic hyperinflation reduces venous return and effective preload, and therefore leads to exaggerated depressions of LV output (and arterial pressure) with each mechanical breath.

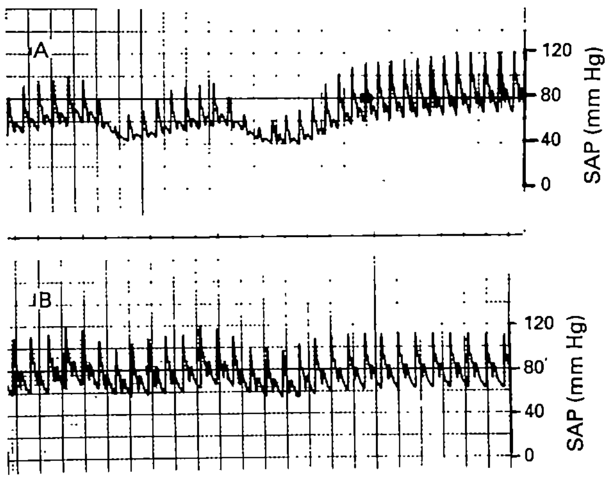

Figure 1 Systolic arterial pressure (SAP) waveform indicating hyperinflation (A), caused by the tip of the tracheal tube abutting on the tracheal wall. Withdrawing the tracheal tube resulted in lung deflation and a normal waveform variation (B).

Such a case is described in figure 1, where hyperinflation (A) was caused by the tip of the tracheal tube abutting on the tracheal wall and causing a one-way valve mechanism. Excessive airway pressure caused the appearance of pronounced SPV with every breath. A short apnoea caused systolic pressure to increase significantly and to be characteristically higher than peak systolic pressure during mechanical ventilation. Withdrawing the tracheal tube resulted in lung deflation and a normal arterial pressure waveform variation (B).

Hence, the appearance of excessive SPV and dDown should indicate frank hypovolaemia or any other mechanism that reduces preload, such as dynamic hyperinflation. The significant increase in systolic pressure during introduction of a short apnoea is indicative of such hyperinflation. In the absence of a direct arterial pressure trace, variations in the plethysmographic signal of the pulse oximeter may reflect the same phenomenon.

Sir,—I appreciate the interesting comments of Perel and Segal who highlight the possible detection of dynamic hyperinflation (DHI) by changes in the arterial waveform with respiratory excursions. Pulse oximetry has also recently been suggested [1], although electronic adjustment of some pulse oximeters makes direct arterial pressure measurement more reliable [2]. Nevertheless, as suggested by Perel and Segal, there are other causes of exaggerated systolic pressure variation (vasodilatation, hypovolaemia) which often coexist after induction of anaesthesia and commencement of positive pressure ventilation. This is when DHI usually manifests. I therefore strongly recommend that DHI is best diagnosed with an apnoeic period, which not only accurately diagnoses the problem, but can quantify the extent of DHI (by measuring the expired gas volume during this period) while offering expeditious treatment. Such an apnoeic period should include insufflation with 100% oxygen and may require more than 90 s for a response [3].

Incidentally, because of the mechanism outlined by Perel and Segal, an apnoeic period may also transiently relieve some of the adverse haemodynamic effects of intravascular volume depletion in patients with obstructive lung disease.

Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia

Sir,—I read with interest the recent report by Robbins, Fernando and Lim on accidental intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia for Caesarean section [1]. Clearly, it is important to report on complications associated with new anaesthetic techniques, such as combined spinal–extradural anaesthesia. I also fully concur with the authors' conclusion that an appropriate test dose be administered through an extradural catheter to exclude intrathecal placement.

However, I believe that the phenomenon of submission bias and publication bias be considered in the interpretation of this report. It is well known that intrathecal migration of an extradural catheter can occur at any time, even without obvious dural puncture. Had such an event occurred during routine extradural anaesthesia (i.e. without combined spinal–extradural anaesthesia), it is unlikely that such a case would have been submitted, and if submitted, it would be unlikely to be accepted for publication. To the authors of this report, and to any others who claim that intrathecal catheter migration is a specific risk of combined spinal–extradural anaesthesia, I challenge that the onus is upon you to prove that this event occurs with any greater frequency during combined spinal–extradural anaesthesia than during routine extradural anaesthesia. In fact, the available evidence in the literature, including large clinical studies [2–4] and laboratory investigations [5], would support the claim that the incidence of intrathecal catheter migration is ***not increased*** when combined spinal–extradural anaesthesia is used. Even outspoken opponents [6] of the needle-through-needle combined spinal–extradural anaesthesia technique have not provided any evidence that this approach increases the risk of intrathecal catheter migration, nor is there any evidence that alternative needle designs decrease the incidence of this occurrence.

When new techniques, such as combined spinal–extradural anaesthesia, are used it is important that complications are documented. However, old, well-known, but infrequent complications of extradural anaesthesia, such as catheter migration, should not be ascribed improperly to new techniques on the basis of isolated case reports. Unfortunately, much of the dogma by which we practise is based on isolated case reports, when large-scale studies would seem to indicate otherwise.

6. Eldor J, Guedj P. Aseptic meningitis due to metallic particles in the needle-through-needle technique. *Regional Anesthesia* 1995; **20**: 360.

Sir,—In a recent case report, Robbins, Fernando and Lim described the presumptive placement of an extradural catheter through the hole made by a 26-gauge Whitacre needle [1].

The authors are correct in stating that only diagnostic studies (MRI or x-ray contrast) can definitively confirm that diagnosis. It is not impossible that bupivacaine 12.5 mg could provide analgesia and increased motor block even if it were injected into the extradural space. We have now seen several cases where CSF could be aspirated from an extradural catheter after a spinal block was made with a 24- or 26-gauge pencil point needle passed through the extradural needle before catheter placement. In one instance, we were so concerned that the catheter was subarachnoid that it was removed and a new catheter was placed one interspace cephalad, at which time some CSF appeared in the hub of the extradural needle (*not* a gush!) and a small amount of CSF could be aspirated through the catheter after it was placed.

After careful evaluation, this catheter was treated as if it were in the extradural space and a continuous infusion of 0.0625% bupivacaine and sufentanil was started. Based on spread and density of block, the catheter appeared to be in the extradural space rather than subarachnoid. This leads us to believe that a small percentage of patients may develop a clinically detectable and immediate CSF leak even when subarachnoid puncture is made with a small gauge pencil point needle. Interestingly, none of our patients developed a clinically detectable post-lumbar puncture headache.

As an aside, we also wonder whether Caesarean should be spelled with a capital C, as it was in this case report. We believe the word derives from the Latin verb for cut and is, in fact, often spelled cesarean, at least on this side of the Atlantic.

1. Robbins PM, Fernando R, Lim GH. Accidental intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia for Caesarean section. *British Journal of Anaesthesia* 1995; 75: 355–357.

Sir,—Thank you for the opportunity to reply to the letters of Dr Camann, and Dr Lee and Professor Abboud regarding our case report [1].

Camann suggests that the risk of migration of an extradural catheter is no greater with combined spinal–extradural anaesthesia than with extradural anaesthesia alone. We have two points to raise on the matter. First, we claimed that the catheter was placed intrathecally and did not migrate to this position. Second, we believe that an extradural catheter will not migrate through intact dura at any time. Holmstrom and colleagues [2] make the point that it is unlikely that an extradural catheter enters a hole made by a spinal needle. By implication such an occurrence is even more unlikely to occur if there is *no* hole made in the dura. We feel that many of these reports may have occurred when the dura was punctured accidentally at some moment by the extradural needle. Even small movements of the needle might cause unintentional damage [3].

We are also not implying that extradural catheter migration is increased with the combined spinal–extradural technique, and agree with Dr Camann that isolated case reports should not prevent its acceptance into practice. However, we do feel that this safe technique is improved by the knowledge that intrathecal catheter placement could occur, and the obvious complications of such placement could be avoided by aspiration and a test dose. In our obstetric unit not only are all elective Caesarean sections performed using combined spinal–extradural anaesthesia, but 75% of all regional blocks for labour analgesia are initiated using the same technique.

Dr Lee and Professor Abboud state that bupivacaine 12.5 mg could have caused the increase in motor and sensory block that we observed after operation, even if it were administered extradurally. We cannot agree with this comment. We gave a 12.5-mg (2.5 ml) injection which, after allowing for the deadspace of the catheter and filter, delivered 7.5 mg (1.5 ml) to the patient. Fink [4] makes the point that it is the length of nerve exposed to local anaesthetic solution that is important. Therefore, it is unlikely that a 12.5-mg (2.5 ml) bolus, let alone a 7.5-mg (1.5 ml) bolus, will have a significant effect if administered into the extradural space, even if sufficient time was allowed.

We agree that some CSF may be seen in the catheter or extradural needle after the spinal needle is removed. This is caused by pressure (especially if the patient is in the sitting position during the combined spinal–extradural anaesthesia) causing CSF to leak out of the spinal needle hole and is not a result of dural puncture with the extradural needle. Based on our continuous positive aspiration and on the speed and density of the block with bupivacaine 7.5 mg, we believe that our catheter was subarachnoid.

Caesarean was spelt with a capital C by the editors of the *British Journal of Anaesthesia*. We have found numerous derivations, including the mechanism of Caesar's birth, and from *Lex Caesarea* (the law of removing a fetus from a dead mother before burying her). Also, the Latin to cut is caedere (with ae) or scalpere. Caesarean may be spelt cesarean in the USA together with anesthesia, pediatrics, labor, and color, but on our side of the Atlantic we believe that we are correct.

RAE tube obstruction during tonsil dissection

Sir,—A 41-kg, 9-yr-old boy was admitted for adenotonsillectomy after recurrent attacks of tonsillitis and frequent bouts of snoring. Penicillin allergy was the only other history of note. Premedication included oral diazepam 6 mg, atropine 0.6 mg and topical EMLA.

A spontaneous breathing technique was planned using incremental injected isoflurane into a low-flow circle system. The trachea was intubated with an RAE 6.5-mm, preformed uncuffed orotracheal tube, and the patient attached to a Datex monitor for full non-invasive cardiorespiratory monitoring. The ENT surgeon inserted a Boyle–Davis gag using an 8.8-cm tongue plate, and examination revealed bilateral hypertrophic tonsils, but absence of enlarged adenoid tissue, and therefore adenoidectomy was unnecessary. Initial surgery and anaesthesia were uneventful but prolonged because of difficult dissection and haemostatic control of the left inferior tonsillar pole. To facilitate easier access and better haemostatic control, the tongue plate used initially was removed and a 10-cm blade inserted. After a few minutes, several events occurred simultaneously; oximetric saturation decreased rapidly, the reservoir bag became partially collapsed, while the surgeon noticed that the RAE tube had herniated through the gap of the tongue plate. Oxygen 100% was administered and a diagnosis of partial tracheal tube obstructed was made. Examination demonstrated that at the point of maximum convexity, the RAE tube had herniated through the gap of the blade, had become kinked and produced flaring of the edges which prevented removal of the tube, but had not caused complete lumen obstruction (fig. 1). Despite several attempts to extricate the RAE tube, it remained jammed in the blade. Therefore, although pulse oximetry returned to normal and tonsillar haemorrhage remained a problem, both RAE tube and gag were removed after pharyngeal suction and cricoid pressure were applied. Re-intubation was performed successfully with the same sized RAE tube, but using an 8.8-cm tongue plate. Subsequent surgery and anaesthesia proved uneventful, and the patient made an uncomplicated postoperative recovery.

The literature describes two reports; Shirley, Kulkarni and Frost [1], and Sen and Gupta [2] both communicated an episode of tube herniation through the Doughty blade during a similar procedure and noted remarkable difficulty in separating the RAE tube from the tongue plate. Contributory factors to tube herniation may have included: the use of a 6.5-mm RAE tube with a 10-cm blade, prolonged surgery causing tube softening and frequent repositioning of the Boyle–Davis gag because of surgical technical difficulties. Prevention of such herniation may include

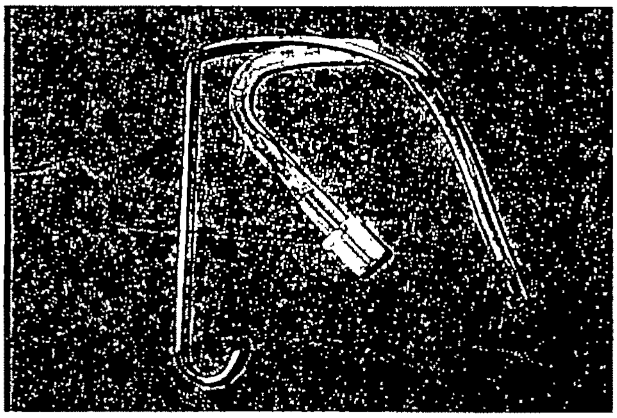

Figure 1 The RAE tube. At the point of maximum convexity, the RAE tube herniated through the gap of the blade, became kinked and produced flaring of the edges.

the use of a more rigid or reinforced tracheal tube [1], a bridge bar, as suggested by Oliver and Rao [3], or the use of a smaller Boyle–Davis gag, as suggested by Baigent and Dunn [4]. This case report not only highlights the need for vigilance during routine elective surgery, but also the value of surgical opinion and communication in helping to alert the anaesthetist to problems during upper airway surgery.

Extradural clonidine for postoperative pain relief

Sir,—I read with interest the article by Lee and Rubin [1] which showed that caudal clonidine 2 μg kg^{-1} with 0.25% bupivacaine 1 ml kg^{-1} improved postoperative analgesia in paediatric patients undergoing lower limb orthopaedic surgery compared with caudal 0.25% bupivacaine alone. Although their results are consistent with another recent report [2], I have recently observed better postoperative analgesia using thoracic extradural clonidine with morphine than morphine alone in adults after gastrectomy [3].

In our study the intensity of pain was assessed by a member of staff who was blinded to the treatment, while each patient received i.v. morphine via a patient-controlled analgesia system as supplementary analgesia. Clinical evaluation of pain is possible in both an objective and subjective manner in adults, but that is not always the case in small children. Based on these considerations, I cannot exclude the possibility that intense sedation induced by extradural clonidine (with local anaesthetics) [4] would make estimation of pain intensity impossible. I also believe that some bias is likely to be introduced in the quantitative assessment of analgesia, especially in paediatric patients, if the patients receive analgesics only when the attending staff judges its requirement.

Porphyria, propofol and rats

Sir,—I read with interest the study of Böhrer and colleagues [1] investigating the porphyrinogenicity of propofol in an induced rat model. I was somewhat surprised by aspects of their study design and subsequent attempts to extrapolate their results to the human anaesthetic state.

In a statement in their summary, an acute porphyric attack was described as largely a dose-dependent phenomenon. Yet, in their study, they chose to induce a state of prolonged sedation (the rats were readily rousable), rather than anaesthesia. This would have obvious inferences on blood propofol concentrations and potential porphyrinogenic effect. The reliance on the i.p. route of drug administration, while technically more convenient than the i.v. route, would imply that blood propofol concentrations were less controllable, and may explain why in the pilot study to establish the dose of propofol, they found it difficult to induce anaesthesia without the problems of irregular respiration and hypothermia. In a similar study, Harrison, Moore and Meissner [2] induced anaesthesia by the i.p. route, followed by maintenance by the i.v. route; this would seem to be a better model to parallel anaesthesia.

While successfully demonstrating another *in vivo* model for biochemical assessment of drug porphyrinogenicity, the study fails to recognize the difficulties of extrapolating such data to the human state. Harrison, Moore and Meissner stated that the behaviour of a drug in an animal model to assess porphyrinogenicity was far removed from proof that it was potentially safe or dangerous to a human sufferer with genetic porphyria. It simply serves to show that in that particular animal model, the drug either displays or fails to display properties known to characterize drugs that do precipitate crises in susceptible humans. Drug metabolism differs profoundly between species; even animals so apparently similar as rats and mice show marked variation in the response of their haem biosynthetic pathway to the effects of various drugs. Disler and colleagues [3] placed this type of work in context, by devising a simple classification of drugs to guide clinicians in the assessment of a drug's porphyrinogenicity.

To attempt to extrapolate such data would be to assume a simple relationship between a drug's ability to induce increased levels of porphyrin precursors in an *in vivo* animal model and its ability to induce a clinical attack. This is clearly not the case. The situation is far more complex, as illustrated by Mustajoki and Heinonen [4] who reported several cases where patients with acute porphyria received various porphyrinogenic drugs (including thiopentone) without clinical effect. This has led to the suggestion that sensitivity to a particular drug may depend on whether or not the patient is in the latent or acute phase of the disease, and on other factors, including endocrine and carbohydrate status at the time of administration.

Finally, the suggested caution regarding the use of propofol for total i.v. anaesthesia and cumulative dosing must also be viewed with some degree of scepticism. Apart for the reasons indicated above, I also suggest a closer review of the case reports used as references. Of the 10 cases, the majority received either repeated boluses or propofol infusions. One patient [5] admitted to the ITU because of neurological sequelae from an acute attack of porphyria received propofol at a dose of 150–200 mg h^{-1} for 32 days without adverse biochemical or clinical effects. Where measured, urinary porphyrin precursors in these studies tended to decrease rather than increase.

5. Harrison JC, McAuley FT. Propofol for sedation in intensive care in a patient with an acute porphyric attack. *Anaesthesia* 1992; **47**: 355–356.

Sir,—The safety of propofol as an anaesthetic agent in human acute porphyrias is well established clinically. With such rare disorders, it is inevitable that most evidence should have been acquired by favourable single case reports (e.g. references [24–32], cited in reference [1]). A prospective study involving 13 patients represents a major confirmation of its safety [2].

Various models of the porphyrinogenicity of drugs in rats, chick embryo or chick embryo liver systems have been devised as a guide to the safety in porphyria of newly introduced therapeutic agents. Direct extrapolation of the findings to humans is not always possible, although some degree of correlation has been obtained with many agents. Before a new drug which has been shown to be highly porphyrinogenic in such a model system is used in a porphyric subject, there would have to be an overwhelming clinical need, not satisfied by available safe drugs. In a similar way, drugs apparently devoid of porphyrinogenic effects in model systems cannot be assumed to be innocuous to porphyric subjects. The gold standard remains careful human evaluation with facilities for early intervention.

Böhrer and colleagues [1] reported a study testing the porphyrinogenicity of propofol in a primed rat model and concluded that "it is a safe agent in the porphyric patient when given as a single bolus dose. Caution may be necessary, however, when large cumulative doses are administered". The logic of this conclusion is difficult to understand, as are the reasons justifying the work: even if their model had shown propofol to be highly porphyrinogenic (as was the case in the primed chick embryos, which they reject as "too sensitive"), this would not have affected its established clinical use. When an anaesthetist has to make a choice, the precedents available from patients would surely prevail over results obtained with 48, or even 48000 rats.

2. Meissner PN, Harrison GG, Hift RJ. Propofol as an i.v. anaesthetic induction agent in variegate porphyria. *British Journal of Anaesthesia* 1991; **66**: 60–65.

Sir,—We appreciate Tidmarsh's and Gorchein's comments on our article which was published recently in *British Journal of Anaesthesia*. We agree with both that there is no straightforward extrapolation of laboratory findings to the clinical setting which can be summarized by the simple expression "humans are not rats".

However, it has been known for many decades that laboratory data may be relevant to the clinical situation. Drugs showing toxic effects in animal models may be used with caution in humans. When applied to porphyria, a drug which caused porphyrinogenic effects in the animal model may be used with more reluctance in the patient. Non-clinical assessment of the porphyrinogenicity of drugs has been made in the chick embryo liver cell culture, in the chick embryo *in ovo* and in rats with experimentally induced porphyria. In our study, we have chosen the *in vivo* rat model which may be more relevant to the clinical situation than the other systems mentioned. In Disler's article quoted by Tidmarsh, the authors categorized drugs according to clinical experience and animal experiments; category A is based on human experience reported by three or more authors, B on human experience reported by one or two authors, C on experiments in rats and D on experiments in cell culture or *in ovo*. In our study, we used spontaneously breathing rats to avoid the hepatic effects of 6 h of mechanical ventilation, and at the end of this 6-h period, blood concentrations of propofol and phenobarbitone were measured to ensure significant levels.

In humans, acute hepatic porphyria is a complex disease. It is a pharmacogenetic disorder with variable penetrance, and acute attacks may be precipitated by a multitude of factors, including stress, infection, starvation, hormone changes and drugs. Variable penetrance implies that there is considerable intra- and inter-individual variability in the response to drugs. One porphyric patient may tolerate a continuous drug infusion over 32 days [1], while others may react adversely to doses of 1225 mg [2] or 1300 mg [3] of propofol. Thus when closely reviewing the case reports quoted and other data available, we believe that propofol can be considered safe when give as a single bolus or even as a double-bolus technique. With regard to the variable penetrance of the disease and the unpredictable occurrence of acute attacks, however, we would not use continuous infusions with total doses greater than 1000 mg in our patients. Moreover, for patients in the latent stage of acute hepatic porphyria, it may be better to avoid general anaesthesia and to offer a regional anaesthetic technique [4] in spite of the occurrence of neuropathological lesions.

BOOK REVIEWS

Baillière's Clinical Anaesthesiology: New Pharmacological Vistas. E. J. FINK JR AND B. B. BROWN JR (editors). Published by Baillière Tindall, London. Pp. 212; indexed; illustrated. Price £30.00.

The present volume consists of a dozen chapters on various topics. These vary from the new inhalation agents, sevoflurane and desflurane, to the use of nitric oxide, blood substitutes and calcium channel blockers, in addition to the usual updates on i.v. agents, opioids and neuromuscular blockers. As is usual with a multi-author book, the style and content vary from chapter to chapter but overall the content is clearly presented and is a very useful update on what is happening in the pharmacological world.

The topics related directly to anaesthesia, such as inhalation agents and antiemetics, contain very little new material but do provide an excellent summary of the available information for those involved in examinations or teaching. Unfortunately, the chapter entitled "New intravenous induction agents" contains an excessive amount of historical data, including sections on etomidate, propanidid and ketamine. Although some of the information is related to the effects of optical isomers and newer formulations, less than one-third of the references cover the past 3 years. Similarly, some of the information on propofol was written as "new" when in fact it has been known for well over 5 years. The only "new drug" in this section is eltanolone, a steroid being developed as a potential follow-up to Althesin. The potential advantage of the agent is favourable safety characteristics, although its clinical role remains to be identified.

In contrast, the two chapters on the new opioid agonists and new agonist–antagonist analgesics contain not only useful reviews of the recent changes in pharmacokinetic and pharmacodynamic thinking, but excellent summaries of some of the newer compounds such as trefentanil, remifentanil, mirfentanil, ciramadol, tramadol and dezocine. Obviously, the pharmacodynamic effects of opioids are similar, with many differences related to changes in the pharmacokinetic characteristics of the drugs. However, the concise summaries are a useful source of information on the differences between new drugs, compared with long individual summaries with no comparative data.

In further contrast, the chapter on nitric oxide provided an excellent formal review of its endogenous role, evidence for selective pulmonary vasodilatation in animal studies and administration in humans as a vasodilator in patients with pulmonary hypertension, as a bronchodilator and in the treatment of hypoxaemia. The author readily recognizes that there are no blinded clinical trials which demonstrate a change in clinical outcome associated with the use of nitric oxide; however, the review provides an excellent starting point to develop such work.

As is common with a book of this type, different sections are appealing to some and not to others. However, the inclusion of broader "medical" reviews such as calcium channel blockers and anaesthetic topics of general relevance such as blood substitutes and α_2 blockers should ensure that the book has a deserving place on library shelves as long as "teachers" and "students" recognize that they may be working from the same volume!

J. E. Peacock

Basics of Transoesophageal Echocardiography. T. D. RAFFERTY (editor). Published by Churchill Livingstone, New York. Pp. 264; indexed; illustrated. Price £65.00.

Transoesophageal echocardiography is receiving ever more attention as a pre-, intra- and postoperative diagnostic and monitoring tool. This book is therefore timely and is written specifically for anaesthetists. The purpose of the book, as defined in the preface, is two-fold. First, to provide the reader with a description of the technical aspects of a basic transoesophageal echocardiographic examination and second, to provide the novice and intermediate practitioner with a clinically orientated source of background information which is necessary for interpretation of the images. In the main, the book succeeds in these two objectives.

The text is divided into four main sections covering basic considerations, the methodology of a two-dimensional echocardiographic patient examination, a section on more specialized techniques and procedures, and finally three chapters on the use of contrast media and training. The diagrams in the book are outstanding in terms of their three-dimensional clarity of interpretation and I cannot think of any other text which provides a better description in terms of both diagrams and words of the way in which the various scan directions are achieved and what they reveal. The illustrations in the book are uniformly of a high quality and there are many which are accompanied by a line diagram to aid interpretation. For someone approaching the subject for the first time, the chapters on two-dimensional echocardiography are excellent. I think the content of the book would provide a good guide to the necessary content of a course on transoesophageal echocardiography for specialist cardiac anaesthetists.

The book does however assume a certain basic knowledge of ultrasound and how it is reflected from tissues and for a book which has the word "basics" in the title it could perhaps be expected that this information would be provided. Consequently, although the book is extremely good in what it sets out to achieve, it would be necessary for someone wishing to obtain a grasp of the subject first to peruse the chapters of a more basic ultrasound text. I also believe that the section on quality assurance should have been introduced at an earlier stage. The need for training and the importance of the dangers of misinterpretation of images is of great importance in this subject. Although these points are made in the last chapter, they could have had more time allocated to them and, in particular, the dangers of misinterpretation given more prominence.

In summary, despite these drawbacks, this book fulfils a definite market need, and it is written by an anaesthetist. Because of this, the text is directed specifically at what anaesthetists and intensivists need to know, and the sections of text describing the various clinical aspects of the subject are in the appropriate proportions. In my view, it would form a valuable addition to the library of any cardiothoracic unit responsible for teaching trainees or any anaesthetist wishing to assess the value of transoesophageal echocardiography in clinical practice.

P. Hutton

Modulation of the Inflammatory Response in Severe Sepsis. J. M. TELLADO, R. A. FORSE AND J. S. SOLOMBIN (editors). Published by Karger, Switzerland. Pp. 188; indexed; illustrated. Price US$ 165.25.

This book is based on the International Symposium held in Madrid in 1993, which discussed modulation of the inflammatory response in severe sepsis. The book consists of 14 main chapters and three appendices. Each chapter is self-contained. The book does not unfold as a continuum but rather as a series of independent reviews.

The breadth and depth of material covered in the book are impressive, extending far beyond the relatively narrow areas of discussion found in mainstream reviews. An introductory chapter describes sepsis in terms of its current definition; this is a clear, easy to read chapter. Subsequently, each chapter covers different aspects of the inflammatory response. These range from the intracellular actions of endotoxins through inducibility of nitric oxide synthase and the role of neutrophils, to more erudite topics such as the influence of agents on the adhesion molecules that allow neutrophil migration.

Interspersed among these topics are chapters on the role of preclinical testing of drugs and design problems in clinical trials for antisepsis drugs. These seem to have appeared almost randomly, but as each chapter stands alone it does not influence the way in which the book is read. The chapters themselves are extremely informative.

This book would be of interest to the research orientated doctor in intensive care. The depth and detail of basic science are impressive. It is an excellent reference manual and provides a good dissertation on the understanding of the inflammatory response in 1993. A criticism of this type of book is always that by the time it is published the field has already moved on, but much of what I read in this book was completely new to me. The reference sections are good and therefore this is an extremely useful book to have on the shelf if the department has an interest in research into the field of inflammatory response.

In summary, this is a book that emphasizes the huge gap between our clinical practice and basic science knowledge. It is a useful reference book for those interested in modulation of the inflammatory response and, in particular, for those with research interests in that field. It may suffer from rapid ageing as the information is already 2 years old. It is probably not a book for the average trainee.

N. Soni

Sedation and Analgesia in the Critically Ill. G. R. PARK AND R. N. SLADEN (editors). Published by Blackwell Science, Oxford. Pp. 216; indexed; illustrated. Price £39.50.

Sedation and analgesia are important areas of intensive care practice that have received little attention in the literature. An overview of this vitally important subject is most welcome and the editors have succeeded in their aim of creating a book aimed at clinicians treating patients. Numerous clinicians from both Europe and the Antipodes have been commissioned to write chapters expanding their own personal views and reviewing the existing literature.

The book is divided into two sections; the first covers the general principles of sedation and analgesia, including indications, pharmacology and assessment of sedation; the second focuses on different types of disease states describing the most effective management of sedation and analgesia in the presence of renal failure, respiratory failure, brain failure, sepsis and trauma. Although there is some inevitable overlap, each contribution is interesting and useful in its own right and the editors and authors are to be commended on the quality of their contributions.

It is my impression that clinical recommendations made about sedation and analgesia in the critically ill are more often based on personal bias and clinical experience rather than on scientific fact. This book provides the clinician with the information that is currently available to allow a rational approach to sedation and analgesia in this group of patients. Perusal of this book would allow a more rational approach to this often neglected area of clinical practice.

D. A. B. Turner

Anaesthesia: Review 11. L. KAUFMAN AND R. GINSBURG (editors). Published by Churchill Livingstone, Edinburgh. Pp. 244; indexed; illustrated. Price £28.95.

This 11th volume in the series is the last to be edited by Dr Kaufman. The format remains much as with previous editions. Dr Kaufman provides an extensive compilation of medical problems affecting anaesthesia in two introductory essays and a final concluding miscellany briefly reviewing a number of topics.

The remaining 10 essays provide valuable reviews on topics ranging from anaesthesia for laparoscopy and the role of transoesophageal echocardiography in anaesthesia to medicolegal problems in anaesthesia and premedication in children. All are practical topics and most clinical anaesthetists will find much to interest and educate themselves. All sections carry comprehensive reference lists.

The essays are valuable in effectively annotating the current literature. They will help candidates for clinical examinations, and the examiners, and keep the rest of us up to date. I hope that Dr Ginsburg will maintain the tradition.

J. Norman

A Practical Approach to Cardiac Anesthesia. F. A. HENSLEY JR AND D. E. MARTIN (editors). Published by Little, Brown and Company, Boston. Pp. 713; indexed; illustrated. Price £52.50.

The aim of this American book is to help the anaesthetist to prepare for and manage cardiac anaesthesia. It is targeted for use in the operating department and intensive care unit by trainees and experienced anaesthetists, and the authors also suggest that it may be a valuable resource for perfusionists. In this second edition, 49 North American authors have contributed to 26 chapters and four sections. The whole book is in note form with many subtitles and lists. It is not referenced comprehensively but there is a suggested reading list at the conclusion of each chapter.

The first section (nine chapters) deals with the anaesthetic management for cardiac surgery, but the information is repeated in several chapters. It represents North American practice, often describes the practice of the individual author(s) and concentrates inadequately on management principles. The chapter on cardiovascular drugs has been expanded since the first edition to include many new drugs. Drugs are grouped according to their physiological properties and then presented alphabetically so that pharmacologically related drugs are separated. However, by relying on the comprehensive index at the start, the chapter becomes more accessible. There is also a chapter on monitoring which is clear and concise.

The second section (six chapters) concentrates on the anaesthetic management of specific cardiac disorders. It includes useful chapters on ischaemic, valvular and congenital heart disease, heart transplantation, electrophysiological disorders and coagulation management. There is also a chapter on surgical emergencies which is of limited value and strays into emergencies which are more appropriate to a book on thoracic anaesthesia.

It is not until the third section (seven chapters) that the basic equipment and techniques of cardiopulmonary bypass are described. The reason for this late introduction is to link in with chapters on mechanical life support devices, and adult and paediatric extracorporeal membrane oxygenation, that is techniques which owe their development to perfusion technology. In this section there are also chapters on the pathophysiology of cardiopulmonary bypass, myocardial and cerebral protection.

The final section (three chapters) contains a useful chapter on thoracic aneurysms and dissections. The final two chapters on the management of thoracic anaesthesia and its pain management are inadequate and (I think) redundant within this book.

The book contains a lot of information within its 700 pages. Its presentation in note form and duplication of information in chapters make it difficult to read and prevent its use as a textbook. However, it was not designed as such. If, as the authors suggest, it is sited within the cardiac unit it will be used as a reference to obtain rapid information on immediate clinical problems.

ERRATUM

British Journal of Anaesthesia 1995; 75: 664P

In the abstract by Driver and colleagues, an error arose in the reported dose of propofol in the second paragraph:
"group 2 received alfentanil 10 μg kg^{-1} 90 s preinduction followed by propofol 2.5 mg kg^{-1}" should read "group 2 received alfentanil 10 μg kg^{-1} 90 s preinduction followed by propofol *1.25 mg* kg^{-1}".

We apologize to the authors for this confusion.

EDITORIAL

Prospects for management of peripheral vascular failure in septic shock

Sepsis remains a major cause of death in intensive care units [1], commonly as the final complication of serious illness, despite adequate antibiotic treatment. Has clinical science any useful new insights into this major medical problem?

The endothelium-derived relaxing factor in blood vessels, reported in 1980 [2], was established later to be nitric oxide or a nitrosothiol. The effects of nitric oxide in regulating vascular tone, platelet function, neurotransmission and host defence have been reviewed recently in this journal [3]. These findings have led to major re-evaluation of the physiological control mechanisms in the peripheral circulation in health and disease, a task by no means complete. So far deficient endothelial release of nitric oxide has been implicated in the pathogenesis of vascular disorders as diverse as hypertension, diabetes mellitus and hypercholesterolaemia [4, 5]. The endothelial or constitutive nitric oxide synthase enzyme (eNOS) continuously replaces this short-lived local regulator, with additional release in response to increased flow velocity in the vessel (shear stress), mechanical deformation or circulating vasodilators.

Excessive production of nitric oxide contributes to the clinical syndrome of gram-negative shock, by causing pathological vasodilatation and reducing the force of myocardial contraction [6]. The main links in this chain of events have been established in experimental animals. Bacterial endotoxin stimulates white cells to release cytokines [7], principally tumour necrosis factor-α (TNFα), interleukins and platelet activating factor (PAF). These cytokines in turn stimulate the expression of genes for inducible nitric oxide synthase (iNOS) in the endothelium, vascular smooth muscle and myocardium, causing overproduction of nitric oxide, which increases the intracellular concentration of cyclic guanosine monophosphate (cGMP) in these and adjacent cells. Vasodilatation results through effects on a variety of ion channels. Recent work implicated the opening of ATP-sensitive potassium channels in hyperpolarizing the smooth muscle cell and dilating the blood vessel. More widespread activation of iNOS has been observed in macrophages, neutrophils, lung, liver [8], kidney and skeletal muscle. This increase in nitric oxide may be in part protective [9].

Doubts have been expressed on the validity of animal models of endotoxaemia, or indeed the role of endotoxin in the clinical syndrome [10]. The current article by Tsuneyoshi, Kanmura and Yoshimura in this issue of the journal [11] establishes in human intestinal arteries *in vitro*, that endotoxin stimulates nitric oxide synthase in the smooth muscle of the vessel wall, in the absence of endothelium or many white cells, and that cGMP-mediated vasodilatation occurs with a loss of responsiveness to the vasoconstrictor actions of noradrenaline. Pretreatment with glucocorticoid reduced the vascular and biochemical changes and maintained responsiveness to noradrenaline. In accord with clinical experience of endotoxic shock, late treatment with glucocorticoids (6 h after endotoxin) was ineffective.

Attempts have been made to block this deleterious pathway at various steps. Competitive antagonism of nitric oxide synthase with analogues of its substrate L-arginine restores vascular responsiveness [12] and arterial pressure in experimental endotoxaemia, but does not necessarily improve the circulatory state of animals [13–15] or patients [3, 16]. Excessive vasoconstriction in the presence of a hypodynamic heart may restore arterial pressure but in doing so may reduce cardiac output further, leading to overall haemodynamic deterioration. Many years ago this problem limited the use of noradrenaline, metaraminol and other vasoconstrictor agents. There is experimental evidence that the excessive vasoconstriction and reduction in cardiac output caused by inhibition of nitric oxide synthase can be reversed in healthy anaesthetized pigs by the addition of selective arterial vasodilators, such as the calcium antagonist nicardipine [17] or the potassium channel opening drug levcromakalim [18]. These results suggested that peripheral resistance could be monitored and controlled at appropriate levels. However, it is less easy to achieve beneficial control and restore cardiac output in pigs treated with endotoxin [19].

The administration of methylene blue, the putative inhibitor of guanylate cyclase, had haemodynamic effects similar to those of inhibition of nitric oxide synthase in patients with septic shock [20].

Non-selective inhibition of nitric oxide synthase also blocks the cytoprotective effects of nitric oxide, and may aggravate tissue damage [9]. The development of drugs which specifically inhibit the inducible form of nitric oxide synthase may preserve the beneficial effects of the constitutive endothelial release of nitric oxide [3, 12, 16]. It remains to be seen whether or not this relatively selective approach will greatly improve the clinical management of established sepsis, as it ameliorates only one end result of many complex processes.

Prevention of the formation of the inducible nitric oxide synthase in vascular smooth muscle and myocardium should be more effective, but would require early intervention or pretreatment. Antibody to the stimulatory cytokines (e.g. anti-TNFα [21] or receptor antagonists to interleukin-1 [22] or PAF [23] reduced the effects of the administration of endotoxin to experimental animals. The clinical potential of such studies is supported by the correlation of lung injury and mortality with high blood concentrations of TNF in patients with septic shock [24]. The use of high doses of glucocorticoids for clinical management of septic shock was suggested 30 yr ago [25]. Among disparate actions, glucocorticoids reduce the expression of inducible nitric oxide synthase and cytokine release [26]. However, clinical experience has been highly variable, and controlled studies of the use of glucocorticoids have shown little benefit [27]. The direct intravascular measurement of nitric oxide in patients should result in more precise understanding of the cause and effect for better clinical management [28].

These developments in the understanding of cellular mechanisms and effects have not yet led to definitive treatment for this common and serious condition. However, there is optimism that further attack on the problem of septic shock with the new methods of molecular biology and cellular physiology will be successful. Advances in gene therapy may permit regulation of the induction of nitric oxide synthase, and control of intracellular mediators in this, as in other cardiovascular disorders [29].

CLINICAL INVESTIGATIONS

Effect of age on MAC in humans: a meta-analysis

W. W. MAPLESON

Summary

It is well known that MAC, the minimum alveolar concentration required to prevent movement in response to surgical incision in 50% of patients, decreases with age. Regression analysis showed that data for humans derived from a comprehensive literature survey were consistent, for age > 1 yr, with $\log_{10}$ MAC decreasing with increasing age at the same rate for all inhaled anaesthetics; approximately equivalent to 6% change per decade of age. With some slight reservation on differences between data from different institutions, the present data for humans are consistent (for age > 1 yr) with the equation $\text{MAC} = a \times 10^{bx}$ where x = difference in age (in years) from 40, $b = -0.00269$ (95% confidence limits (CL) −0.0030, −0.0024) and a = MAC at age 40 yr, which, for anaesthetics currently in use clinically, is given by: halothane, 0.75%; isoflurane, 1.17%; enflurane, 1.63%; sevoflurane, 1.80%; desflurane 6.6%; nitrous oxide, 104%; with 95% CL of approximately ±7% (±10% for desflurane, ±17% for enflurane). (*Br. J. Anaesth.* 1996; **76**: 179–185)

Key words

Anaesthetics gases. Anaesthetics volatile. Potency, anaesthetic, MAC. Age factors.

MAC has been defined as "the minimum alveolar concentration of anaesthetic at 1 atmosphere that produces immobility in 50 per cent of those patients or animals exposed to a noxious stimulus" [1]. There is the rider [1] that the alveolar concentration must have been held constant for long enough for the brain to come into equilibrium with the alveolar concentration. In humans, the stimulus is normally surgical incision.

It is well known that MAC decreases with age and some authors [2–5] have drawn attention to similarities between agents in the trend of MAC with age. A need to express measured end-tidal concentrations of halothane, enflurane and isoflurane in terms of MAC units in patients of different ages [6] provided the stimulus to try to derive, from published data, a general equation to represent the dependence of MAC on age. Thus, in the terms of Andersen [7], this is an "inductive, hypothesis-generating" study, not a hypothesis-testing one.

Methods

SELECTION OF DATA FOR ANALYSIS

The selection was restricted to peer-reviewed investigations which used inhalation induction and, with one exception, no premedication or only atropine, and which reported, for each group studied, the number of patients, mean age and the value of MAC derived. Data for alternative forms of MAC, such as MAC for tracheal intubation [8], and MAC based on "grimace or movement" [9] rather than only on movement, were excluded: although the dependence of the grimace variant of MAC on age seems very similar to that of conventional MAC, MAC for tracheal intubation under sevoflurane appears to *increase* with age [10, 11]. Similarly, values for MAC derived from movement in response to electrical stimulation were excluded because there is some evidence [12] that they may not be consistent with values based on response to surgical incision.

Literature searches in the Embase and Medline databases, together with examination of the citations in the resulting papers, yielded a total of 30 articles [2–5, 10–35] containing data that met the selection criteria. These included nine articles from which indirect estimates of MAC for nitrous oxide were derived (appendix). Direct estimate in volunteers at hyperbaric pressures [36] was not used because this was based on the response to electrical stimulation.

STRATEGY FOR COMBINING DATA FROM DIFFERENT STUDIES

Only one article [12], from Berne at 500 m above sea level, reported a correction (−6% of MAC) for altitude, as the definition of MAC is in terms of the concentration of anaesthetic *at 1 atmosphere* [1]. For the present study, corrections were also applied to results from studies conducted at more than 100 m above sea level: Iowa −2.5%; Durham, North Carolina (Duke University), −1.5%; Milan −1.5%.

All estimates of MAC were included in a multiple linear regression analysis. Because of the wide range of MAC values between different anaesthetics (more than 100 to one), $\log_{10}$ MAC was used as the dependent variable. Individual estimates of MAC were generally weighted in proportion to the number of patients included in each group (appendix).

W. W. MAPLESON, DSC, FINSTP, Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff CF4 4XN. Accepted for publication: October 2, 1995.

Inspection of the data suggested that values of MAC for children, especially those less than 1 yr of age, might be inconsistent with the trend for adult data; therefore analyses were performed for all ages, age > 1 yr and age > 18 yr.

For each of these three analyses, three versions of the regression were tried, on the basis of three different assumptions.

(1) All estimates of MAC for a given anaesthetic are equally valid (apart from the weighting). For this version, a set of parallel lines was fitted, one for each anaesthetic. This used all of the data.

(2) There may be differences between institutions because of slightly different techniques or because different populations were sampled. This version required a separate parallel line for each institution within each anaesthetic. This is equivalent to basing the slope only on data from those institutions that have studied more than one age group.

(3) There may be differences even between studies within the same institution. This version required a separate parallel line for each study. It involved basing the slope only on data which included more than one age group in a single study.

Within each of these three versions, evidence of curvature of the regression of log MAC on age was sought by adding $(\text{age})^2$ and $(\text{age})^3$ to the predictor terms, and evidence of differences between anaesthetics in the dependence of log MAC on age by allowing a separate slope for each agent.

Each elaboration or restriction of the model was tested for improvement of fit and adopted only if it yielded $P < 0.05$. This is a regression equivalent of a procedure [37] for testing for consistency of groups in a meta-analysis of means.

Further inspection of the data showed that only one study (for halothane [14]) included data for children in addition to adults, and that this study would have a dominant effect on the results of the one-line-per-study analyses. However, there were two instances where one anaesthetic (sevoflurane) was the subject of two studies from the same institution, with one or more authors in common, published in the same or consecutive years, with one dealing with children and the other with adults. Therefore, for the purpose of the analyses, each of these pairs of studies ([10, 11] and [5, 27]) was treated as a single study.

The statistical package used was GLIM 4, [38, 39] update 8, on a DEC mainframe computer under the Ultrix operating system OSF/1 V3.0.

Results

The input data derived from the literature survey are listed in table 1.

Table 1 Data derived from the literature. w = Weight assigned to each MAC value, usually the number of patients involved, but see appendix. UCSF = University of California, San Francisco; UCSD = University of California, San Diego; Univ. = university. *Individual age data available. †The negative ages refer to preterm neonates and correspond to the degree of prematurity. MAC values are generally as quoted in the original references (for a logistic regression estimate where there was a choice) but reduced to sea level for institutions above 100 m altitude (see appendix for nitrous oxide values)

Regression analyses showed that, whichever age range was included (all, > 1 yr, > 18 yr), it was essential to allow a separate line for each institution (P always < 0.0006) but not for each study (P always > 0.06). With one line per institution (or one per study) there was a strong improvement in fit by restricting age to > 1 yr ($P < 0.0001$) but little further improvement on restricting to > 18 yr ($P > 0.09$). There was no significant curvature in any

Table 2 Fitted MAC at ages 1, 40 and 80 yr (based on data for age > 1 yr) with confidence limits (CL). w = Total weight (see appendix) for each anaesthetic (or institution). MAC for other ages (> 1 yr) can be calculated according to equation (2) where b is given by equation (1), x = difference in age (in years) from 40 yr, and $a(i,j)$ = MAC at age 40 yr for anaesthetic i and (where appropriate) institution j. *Institution (see table 1)—where more than one institution has reported MAC values for age > 1 yr. †CL at 1 and 80 yr are up to 1 % of MAC greater. ‡Single MAC value for each age, based on all data for that anaesthetic for age > 1 yr

model, except for one line per institution using all ages ($P = 0.03$), nor any significant difference in slope between anaesthetics.

Thus the optimum model was that with the data restricted to age > 1 yr, and with a separate parallel straight line for each institution for each anaesthetic. This gave a slope of $\log_{10}$ MAC on age of:

$$b = -0.00269\ \text{yr}^{-1} \qquad (1)$$

with 95 % confidence limits (CL) of −0.0030 and −0.0024, that is ±12 %. This corresponds to a change in MAC of approximately 6 % per decade of age or, more precisely, a 22 % decrease from 40 to 80 yr of age and a 27 % increase from 40 to 1 yr of age.

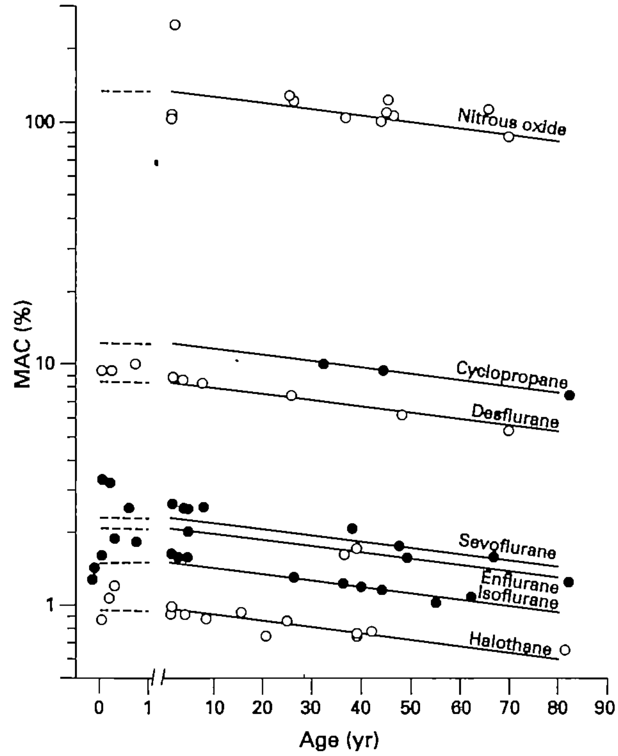

Figure 1 Effect of age on MAC: comparison of fitted lines with published values. Continuous lines = fitted values, from 1 to 80 yr, for each anaesthetic as a whole, based on data for age > 1 yr; broken lines = extrapolation to age zero. The bias and extra scatter of published values about these extrapolations draw attention to their invalidity (see text). A 10-times expanded time scale has been used for ages less than 1 yr to separate the many published values in that age range. The symbols, (○) and (●) are used for alternate anaesthetics. Five agents are omitted to avoid cluttering the diagram: for each agent, only a single estimate of MAC was available and the fitted line necessarily went through that value.

To avoid explicitly stating a notional, but misleading, MAC at age 0, it is preferable to express the results relative to MAC at some intermediate age. Forty years has been chosen as a convenient midpoint. Thus, the overall results can best be summarized by the equation:

$$\text{MAC} = a(i,j) \times 10^{bx} \qquad (2)$$

where x = *difference* in age (in years) from 40 yr, b = slope of $\log_{10}$ MAC on age (equation (1)), and $a(i,j)$ = fitted value of MAC at 40 yr of age for anaesthetic i and (where appropriate) institution j (table 2). It must be stressed that the equation is not valid for age < 1 yr. The residual SD of the data points about the fitted lines was 0.0179 in terms of $\log_{10}$ MAC, corresponding to 95 % of the points lying within ±8 % of the one-line-per-institution predicted values.

The implications of this equation are illustrated in table 2, which lists fitted values of MAC for each institution at 40 yr of age and for each anaesthetic as a whole at ages 1, 40 and 80 yr. These "global" values were obtained by forcing the fitted slope (equation (1)) on all data for each anaesthetic but allowing only a single intercept—a single $a(i)$. Confidence intervals (95 %) are given for 40 yr of age; confidence intervals at ages 1 and 80 yr are up to 1 % of MAC greater. With these global lines (one per anaesthetic) the discrepancies between institutions have increased the residual SD of the data points to 0.0453, corresponding to 95% of the points lying within −18%, +23% of the global, one-line-per-anaesthetic, predicted values. Strictly, this applies only to points which have the average weight (for age > 1 yr) of 17; points with lower weight ("w" in table 1), as with many of the nitrous oxide values, have a wider scatter and vice versa.

Conformity of the original data to the fitted regression lines is shown in figure 1. The main part of the graph shows measured values and fitted lines for age > 1 yr; the left of the graph shows extrapolation to zero age (broken lines), and measured values for age < 1 yr, on a 10-times expanded age scale (hence the flatter slope of the broken lines). To avoid cluttering the graph, data for five agents have been omitted: each of those lines would simply go through the one measured value.

Discussion

The available data are consistent with the hypothesis that all inhaled anaesthetics have a common slope of $\log_{10}$ MAC on age, for age > 1 yr, but that there may be differences between institutions in MAC for an anaesthetic, for any particular age. A theory of why a common slope is not surprising is given in the appendix.

A common slope for *log* MAC on age is consistent with the findings that the change in linear MAC with age is the same for several agents only if MAC for each agent, at any age, is expressed as a percentage of MAC for that agent at some standard age [2, 3], or if some equivalent scaling manoeuvre is used [4, 5].

These findings are not contradicted by the observation [3] that the slope of MAC on age for a volatile anaesthetic, when combined with a fixed concentration of nitrous oxide, is steeper than that for the volatile alone. This arises because the fixed concentration of nitrous oxide represents a larger fraction of MAC at the greater age; therefore a smaller fraction of MAC needs to be supplied by the volatile agent.

The difference in fitted MAC between institutions might be attributable to the sampling of different populations. There is some evidence in table 2 of MAC values from North America being greater than those from Europe (isoflurane and enflurane) or Japan (sevoflurane), but there are comparable or wider differences between institutions within North America (halothane, isoflurane, desflurane and nitrous oxide) or Japan (sevoflurane). Also, part of the difference in the case of isoflurane could be attributed to the use of temazepam 20 mg orally as premedication in one of the European studies [22]. Therefore, the differences may all be attributable to slight variations in technique, including differences in the absolute calibration of the gas analysers used. It is on this basis that a "global" value is given for each of these anaesthetics in table 2 and global fitted lines are plotted in figure 1.

It is the residual SD of the (age > 1 yr) data points around these global lines (corresponding to 95% of the points lying within approximately ±20% of the predicted values) which has been used in calculating the confidence limits in table 2. Apart from a small addition arising from uncertainty over the slope of the dependence on age, the confidence limits at age 40 yr, as a percentage of MAC, are equal to approximately $20 \times \sqrt{(17/w)}$, where w = total weight for the anaesthetic (usually the number of patients studied) and 17 is the average weight per MAC value in table 1 for age > 1 yr. For each anaesthetic which has been the subject of only one study, with 15 to 28 patients, the confidence limits are considerably wider than any derivable from the study itself. This is because the confidence limits in table 2 allow for the general variability between studies and between institutions, which variability is absent from the results of any one study.

The left-hand part of figure 1 shows that, for ages less than 1 yr, the proportion of measured values lying within −18%, +23% of the extrapolations of the regression lines is not 95% but only 70% (10 of 14). Until recently it was possible to argue [34] that there was a consistent trend for young children, with MAC reaching a peak at around 6 months of age, but recent data on sevoflurane in this age range [31] appear to contradict this. The poor agreement with extrapolations of the global lines could be reduced by postulating a steepening of the lines in the early years of life. Certainly, the mainly non-significant curvatures found in the regression analyses were mostly in this direction. The remainder of the scatter could then be attributed to most of these MAC values being based on only 12 patients each, instead of the mean of 17 for age > 1 yr. However, it is clear that further studies in this age range, with larger numbers of patients, are needed to resolve the discrepancies.

As MAC is defined in terms of anaesthetic concentration at 1 atmosphere, corrections should be applied, not only for the systematic effect of altitude (as was done in this analysis), but also for day-to-day variations in barometric pressure. This could not be done because none of the studies reported barometric pressure. The range of barometric pressure amounts to about ±5% (about 95–105 kPa at sea level), but each study would be spread over at least several days so that mean pressures for different studies would generally vary less than this. Therefore, this can account for only a small fraction of the scatter in figure 1. However, it is probably unwise to draw conclusions from differences of less than 5% between studies.

A further source of uncertainty is the difference between end-tidal and arterial partial pressure because it is the latter with which the site of action of the anaesthetic will equilibrate. This difference can be expected to vary with the degree of ventilation–perfusion mismatch in the lungs and so account for some of the scatter in figure 1. However, even if all studies were carried out in terms of arterial partial pressure, this would not be very helpful clinically because such measurements are not generally available.

A few studies (* in table 1) reported full data for each individual patient: end-tidal concentration, age and whether or not the patient moved. With such data it is possible, in principle, to obtain an estimate of MAC, and also its dependence on age, from a single study. This can be done using logistic regression or probit analysis to predict "not move" from both log concentration and age. When this was tried, it was found that most individual studies failed to show a significant dependence on age because each covered only a small range of ages. However, combining the results from the nine groups of patients receiving only a volatile anaesthetic, and using a separate intercept for each institution, gave a slope of $-0.00288 \log_{10}$ MAC yr^{-1} compared with the present -0.00269, and confidence limits of $\pm 27\%$ (based on 182 patients, a weight of 182 as defined in the appendix) compared with the present $\pm 12\%$ (around one line per institution and based on a weight of 993).

The ratio of these two percentage confidence limits (2.25) is nearly the same as the ratio of the square roots of the two weights (2.34), and therefore overall there is no particular advantage in one technique over the other. However, the logistic or probit technique would have an advantage within a single large study: if it is desired to determine MAC for a range of ages, the current procedure is to study say 20 patients in each of three or four age groups, determine MAC for each group, and perhaps fit a line to the three or four results leading to a slope with a standard error which would have only one or two degrees of freedom. Instead, it would be better to handle all the results in one analysis to predict the probability of movement from log concentration and age so that the standard error of the slope on age would have almost as many degrees of freedom as the number of patients studied.

Stewart and Parmar [40] have demonstrated the advantages of "meta-analysis of individual-patient data" (MAP) compared with "meta-analysis of the literature" (MAL) in the context of survival studies. The main analysis in this article, using just MAC and mean age from each study group, is an example of MAL; logistic analysis of those studies which gave full data on individual patients is an example of MAP. Therefore, the fact that the two "MAP/MAL" ratios (ratio of percentage confidence limits and ratio of the square roots of the weights) were so similar suggests that MAP has no advantage over MAL in the present context, unless additional information was obtained from the original authors, as Stewart and Parmar did.

In conclusion, it is suggested that the parallel lines defined by equations (1) and (2), and the numerical values in table 2, represent the current best estimates of MAC, and its dependence on age, for the 12 inhaled anaesthetics listed, and for age > 1 yr. However, the present data allowed only limited testing of differences in slope between anaesthetics or in intercept between institutions or studies so it may be that, as more data are accumulated, the true picture will prove to be more complex. In the meantime, the present global regression lines provide a consistent basis for expressing measured concentrations of these anaesthetics as fractions or multiples of MAC at any age > 1 yr. The lines are typified by the values for isoflurane: MAC = 1.49% at age 1 yr, 1.17% at 40 yr and 0.91% at 80 yr.

Appendix

DERIVATION OF MAC FOR NITROUS OXIDE

Several articles give values for MAC for a volatile anaesthetic, and for the same volatile agent when mixed with a fixed concentration of nitrous oxide. It now seems clear [41], despite earlier doubts [42, 43], that the current inhaled anaesthetics are additive in their effects. Therefore, it is possible to estimate MAC for nitrous oxide from:

$$\text{MAC}_{\text{N}_2\text{O}} = F\text{E}'_{\text{N}_2\text{O}}/\{(F\text{E}'_{\text{vol2}} - F\text{E}'_{\text{vol1}})/F\text{E}'_{\text{vol2}}\}$$

where $F\text{E}'_{\text{N}_2\text{O}}$ = fixed end-tidal concentration of nitrous oxide, and $F\text{E}'_{\text{vol1}}$ and $F\text{E}'_{\text{vol2}}$ = end-tidal concentrations of volatile agent required to prevent movement in 50% of patients, with and without nitrous oxide, respectively. This has been done here for six studies [3, 4, 28, 31–33]. In three further studies where a volatile anaesthetic was combined with two or more concentrations of nitrous oxide [19, 24, 26], MAC values for both agents can be obtained by extrapolation to zero volatile concentration for nitrous oxide and, where necessary [26], to zero nitrous oxide concentration for the volatile agent.

In studies where only the inspired concentration of nitrous oxide has been reported, the end-tidal concentration has been taken to be 0.97 of the inspired concentration to allow for a theoretical [44] 3% incomplete equilibration of alveolar with 70% inspired nitrous oxide at 20–30 min after the start of administration. Where only the carrier gas concentration has been reported, the inspired concentration has first been estimated by multiplying by $(1 - F_v)$ where F_v = fractional concentration of the volatile agent in the nitrous oxide—volatile mixture.

WEIGHTING OF STUDIES

The best method of combining a number of estimates is to weight each in proportion to the reciprocal of its variance: this leads to a minimum-variance combined estimate [45]. Standard errors, where they are reported in the literature, vary widely and this is likely to be, at least in part, because of the relatively small numbers of patients in any one group and probably to different methods of estimating SE. Therefore, it is assumed here that the variability between patients is inherently a constant, and the same for all inhaled anaesthetics. On this basis, the appropriate weighting of the mean age data can be achieved by making the weight of each estimate of MAC proportional to the number of patients on which it is based.

In the case of nitrous oxide, most estimates of MAC are derived from the difference between MAC values for a volatile in two groups of patients, with and without nitrous oxide (or with two different concentrations of nitrous oxide). The variance of a difference is the sum of the two variances, so the appropriate weighting is $n/2$, where n = number of patients in each group, or $(n_1^{-1} + n_2^{-1})^{-1}$, when the numbers n_1 and n_2 in the two groups are unequal. For each of the two studies [19, 24] which obtained MAC for nitrous oxide in children by extrapolation to zero concentration of the volatile anaesthetic, three differences were involved. Therefore, the variances of each of the resulting estimates of MAC for nitrous oxide can be thought of as each arising from the mean of three differences; therefore the estimates were assigned weights of $3n/2$ (where n = number of patients in each group) as a tolerable approximation for the purpose of the present analyses.

THEORY

It is well known that MAC for inhaled anaesthetics is closely, negatively, correlated with the oil/gas partition coefficient λ [46]. Using the present fitted values of MAC (in percentages) at age 40 yr, and the values of the ratio λ from Halsey [47], leads to a mean value for $\lambda \times$ MAC of 130 with an SD of 28—a coefficient of variation of 20%. Compared with the range of MAC values between different anaesthetics (a ratio of 650 between the largest and smallest) this is small. As many investigators have noted [46], this suggests that the site of action of inhaled anaesthetics is lipid-like.

Assume that for any one of the 12 anaesthetics studied here, the concentration C_s at the site of action (for no movement in response to the surgical incision in 50% of patients) can be represented by

$$C_s = \lambda_s \times \text{MAC}$$

where λ_s = site/gas partition coefficient for that anaesthetic.

Assume also that C_s is the same for all 12 anaesthetics (at any given age) and that, for each anaesthetic, λ_s is independent of age. Then, for any two inhaled anaesthetics i, j, at any two ages a, b,

$$C_{sa} = \lambda_{si} \times \text{MAC}_{ia} = \lambda_{sj} \times \text{MAC}_{ja}$$

and

$$C_{sb} = \lambda_{si} \times \text{MAC}_{ib} = \lambda_{sj} \times \text{MAC}_{jb}$$

Therefore,

$$\frac{\text{MAC}_{ia}}{\text{MAC}_{ib}} = \frac{\text{MAC}_{ja}}{\text{MAC}_{jb}} = \frac{C_{sa}}{C_{sb}}$$

whence

$$\log \text{MAC}_{ia} - \log \text{MAC}_{ib} = \log \text{MAC}_{ja} - \log \text{MAC}_{jb} = \log C_{sa} - \log C_{sb}$$

that is the decrease in logMAC from age a to age b is the same for anaesthetics i and j, and therefore for all 12 anaesthetics.

Thus the current finding of a common slope of log MAC on age for all 12 anaesthetics is to be expected if the concentration required at the site of action is the same for all anaesthetics and if each λ_s is independent of age. The mathematics can readily be extended to include the case of λ_s being dependent on age but with $\log \lambda_s$ having the same slope on age for all 12 anaesthetics.

The above argument is a long way from proving that the variation of MAC with age should be the same for all anaesthetics, but it does show that the present result is not surprising.

Omitting nitrous oxide in general anaesthesia: meta-analysis of intraoperative awareness and postoperative emesis in randomized controlled trials

M. TRAMÈR, A. MOORE AND H. MCQUAY

Summary

We have reviewed randomized controlled trials to assess the effectiveness and safety of anaesthetics which omitted nitrous oxide (N_2O) to prevent postoperative nausea and vomiting (PONV). Early and late PONV (6 and 48 h after operation, respectively), and adverse effects were evaluated using the numbers-needed-to-treat (NNT) method. In 24 reports with information on 2478 patients, the mean incidence of early and late vomiting with N_2O (control) was 17% and 30%, respectively. Omitting N_2O significantly reduced vomiting compared with a N_2O regimen; the combined NNT to prevent both early and late vomiting with a N_2O-free regimen was about 13 (95% confidence intervals (CI) 9, 30). The magnitude of the effect depended on the incidence of vomiting in controls. In studies with a baseline risk higher than the mean of all reports, the NNT to prevent both early and late vomiting with a N_2O-free anaesthetic was 5 (95% CI 4, 10). When the baseline risk was lower than the mean, omitting N_2O did not improve outcome. Omitting N_2O had no effect on complete control of emesis or nausea. The NNT for intraoperative awareness with a N_2O-free anaesthetic was 46 compared with anaesthetics where N_2O was used. This clinically important risk of major harm reduces the usefulness of omitting N_2O to prevent postoperative emesis. (*Br. J. Anaesth.* 1996; **76**: 186–193)

Key words

Anaesthetics gases, nitrous oxide. Vomiting, nausea. Memory. Vomiting, nausea, anaesthetic factors. Anaesthesia, audit. Anaesthesia, depth.

Theoretically, nitrous oxide (N_2O) is an emetic and it is generally believed to be associated with postoperative nausea and vomiting (PONV). N_2O penetrates easily into closed spaces such as the bowel [1, 2] or middle ear [3–5], activates the medullary dopaminergic system [6] and increases cerebrospinal opioid peptides [7]. In humans, N_2O analgesia was shown to be reversible by naloxone [8]. These data suggest that N_2O could induce PONV through at least three mechanisms and experimental studies with N_2O reported nausea and vomiting in healthy volunteers [9–11].

The effect of N_2O on the incidence of PONV is controversial [12]. Palazzo and Strunin classified N_2O as an agent known to cause PONV, claiming that the most likely mechanism was gastrointestinal distension by manual ventilation and N_2O transfer to the gastrointestinal tract [13]. Others questioned a decrease in the incidence of PONV when N_2O was omitted in halogenated inhalation anaesthetics, but suggested that omitting N_2O in propofol anaesthesia may be beneficial [14].

This meta-analysis of randomized controlled trials (RCT) tested the evidence that general anaesthetics which omit N_2O are associated with a decreased incidence of PONV. Statistical and clinical significance of the effect of N_2O-free anaesthetics on PONV compared with regimens including N_2O, and anaesthesia-related complications were evaluated using odds ratio and number-needed-to-treat (NNT) methods.

Methods

Medline was searched (1966 to May 1995) without language restriction for RCT which evaluated the effect on PONV of a N_2O-free anaesthetic (treatment) compared with the same anaesthetic but including N_2O (control). Key words used were "nitrous oxide" and "vomiting" or "nausea". Additional reports were identified from the reference lists of retrieved trials and from review articles of PONV. Unpublished studies were not sought. Each published report which could possibly be described as an RCT was read independently by each of the authors, who scored the reports for quality using a three item scale [15] and then met to agree consensus scores. All RCT reporting emetic outcome as dichotomous data were included. Studies without randomization and abstracts were not considered.

Information on patient characteristics, surgery, anaesthetics, definition of emesis and adverse effects was obtained from each report. Dichotomous data of the incidence of early PONV (up to 6 h after operation) and late PONV (up to 48 h after operation) were extracted. When several incidences of PONV were reported at different times (time intervals, for instance [16]) the two cumulative values nearest to 6 h and 48 h after operation were analysed. Effectiveness was defined as absence of emesis. Complete control of emesis was analysed when

Correspondence to M.T.

mentioned specifically in the reports (number of patients without any emetic symptoms, for instance). The incidence of nausea and vomiting was analysed separately when reported. Retching, when reported as a separate outcome, was added to the incidence of vomiting. No weighting was used for different grades of nausea, number of vomiting episodes, time to first vomiting episode, number of patients needing antiemetic rescue therapy or delay until discharge. The incidence of intraoperative awareness was recorded as indicated in the reports.

Odds ratios (OR) with 95 % confidence intervals (95 % CI) were calculated using a fixed effects model. NNT and 95 % CI were calculated [17]. This was done for effectiveness and adverse effects, both for individual reports and by combining single treatment or control arms. A statistically significant improvement in a N_2O-free regimen compared with control was assumed when the lower limit of the 95 % CI of the OR was > 1. In the text, NNT for effectiveness and adverse effects are reported with 95 % CI only when the OR indicated a statistically significant improvement in the treatment compared with control. Point estimates of the NNT without 95 % CI are reported when the OR was not statistically significant. An infinite value for NNT indicates a negative value. Calculations were performed using Excel v 4.0 on a Macintosh IIci.

Results

REPORTS

We identified 32 publications. Our search strategy detected 17 reports from Medline. Eight trials were excluded; one was not randomized [18], five had an inadequate randomization method (alternate allocation [19]; patient's date of birth [16, 20, 21]; patient's registration number [22]), and in two the emetic outcome was not reported as dichotomous data [23, 24]. One RCT without dichotomous PONV data was included in the awareness analysis because recall was an outcome [25].

The 24 analysed reports contained data on 2478 patients. N_2O and PONV interactions were evaluated with isoflurane (eight trials), enflurane (three), halothane (three), desflurane (five) and propofol (six). In the three largest RCT, more than 680 patients had a N_2O-free anaesthetic with either isoflurane [26, 27], enflurane [26] or halothane [28]. In three studies, about 50 treated patients were analysed in each treatment arm [29–31]. In each of the remaining 18 studies, N_2O and PONV interactions were investigated in no more than 35 patients who had a N_2O-free anaesthetic [1, 25, 32–47]. Tables containing information extracted from all trials are available from the authors.

OUTCOMES

Complete control of emesis with no emetic symptoms in the postoperative period was reported in four studies. In two studies, this was the only emetic outcome [36, 45]. For both early and late complete emetic control, there was no significant improvement in N_2O-free techniques compared with control (table 1).

Nausea as a separate outcome was reported in 14 studies. In one study this was the only emetic outcome [1]. Omitting N_2O had no impact on early or late postoperative nausea (table 1).

The incidence of vomiting, with or without retching, was reported in 19 studies. In four studies this was the only emetic outcome [27, 28, 37, 46]. For early and late times, the mean incidence of vomiting in controls was 17 % and 30 %, respectively. For early vomiting, anaesthetics which omitted N_2O produced statistically significant improvement over control and the combined NNT to prevent early vomiting was 11.8 (8.5, 19.4) (table 1). For late vomiting, N_2O-free regimens also produced a statistically significant improvement over control, and the combined NNT to prevent late vomiting was 13.8 (8.8, 31.6) (table 1).

EFFECT OF BASELINE RISK ON OUTCOME

All three large studies reported vomiting as a separate outcome [26–28]. In two the incidence of vomiting in controls was less than 10 % for early and only 13.3–28.7 % for late vomiting [26, 28]. NNT point estimates were 29 and 105 to prevent early vomiting and 30 and 305 to prevent late vomiting. The third reported a high baseline risk for late vomiting in controls (46 %) and the NNT point estimate to prevent vomiting with a N_2O-free regimen was 8.5 [27].

When all trials reporting vomiting as an outcome were analysed baseline risks of vomiting and corresponding NNT to prevent vomiting by omitting N_2O showed an inverse relationship (figs 1, 2). Combined analysis of trials with a baseline risk lower than the mean of all trials showed no improvement in the N_2O-free groups over controls (tables 2, 3). In this subgroup, the mean baseline risk was very low; 7 % (range 0–13 %) for early and 20 % (0–29 %) for late vomiting. Combined analysis of trials with a baseline risk higher than the mean showed statistically significant improvement of the N_2O-free regimens over control (tables 2, 3). In this subgroup, the mean baseline risk was high; 35 % (21–50 %) for early and 51 % (43–71 %) for late vomiting, and the NNT to prevent early and late vomiting with a N_2O-free technique were 4.8 (95 % CI 3.6, 7.3) and 5.6 (3.9, 10.1), respectively. Anaesthetic techniques and types of surgery were similar in the subgroups (tables 2, 3).

Subgroups were different from each other in terms of risk reductions and NNT to prevent vomiting with a N_2O-free technique (tables 2, 3). For early vomiting the risk reduction was twice, and for late vomiting it was three times higher in studies with a high baseline risk of vomiting compared with those with a low risk (tables 2, 3). The corresponding NNT to prevent vomiting with a N_2O-free technique were 8–12-fold different.

When the three large studies [26–28] were excluded from the subgroup analysis the inverse relationship between incidence of vomiting in controls and corresponding NNT to prevent vomiting

with a N_2O-free anaesthetic was maintained (tables 2, 3).

PROPOFOL

The incidence of vomiting was analysed separately in five studies investigating N_2O and propofol interactions [29, 35, 34, 42, 46]. For both early and late vomiting, a total i.v. anaesthetic (TIVA) with propofol led to a statistically significant improvement compared with a propofol–N_2O regimen (lower 95% CI of the OR 1.1 for early and 1.4 for late vomiting, respectively). The NNT to prevent early vomiting with a propofol-based TIVA was 10.4 (5.4, 149) in four studies with 94 treated patients [34, 35, 42, 46]. The NNT to prevent late vomiting was 7.4 (4.5, 22) in four studies with 134 treated patients [29, 35, 42, 46]. Only one study reported statistically significant improvement in the N_2O-free propofol anaesthetic compared with control for both early and late vomiting [46]. Another study reported statistically significant improvement in the N_2O-free regimen for late but not for early vomiting [42]. In both reports the incidence of vomiting in controls was high; 47% for early and 44–60% for late vomiting [42, 46].

INTRAOPERATIVE AWARENESS

One RCT reported intraoperative awareness in six of 134 patients in the N_2O-free group and in one of 126 in the control group [27]. Patients in this study were premedicated with triazolam. In one study without premedication, one incidence of recall was reported in 31 patients in the N_2O-free group [43]. Five studies reported explicitly the absence of intraoperative awareness in the N_2O-free groups [25, 30, 34, 36, 47]. The NNT for one patient experiencing intraoperative awareness with a N_2O-free anaesthetic compared with a regimen with N_2O was 46.2 (24.1, 581); the odds ratio was 4.5 (1.1, 18).

Discussion

The controversy on the effect of N_2O on PONV [48, 49] may result from three problems. First, most data from N_2O and PONV interactions are based on small studies and some showed statistically significant improvement with N_2O-free regimens [30, 31, 37, 46, 47] whereas large studies involving hundreds of patients did not show any difference [22, 26, 28]. Second, pharmacological antiemetic effectiveness can be reported as absence of nausea, of vomiting with or without retching, or of any emetic event (i.e. complete emetic control). Some studies reported only one of these outcomes. However, the effect of N_2O on these emetic outcomes was shown to be different. Finally, the confusion about N_2O and PONV interactions may simply reflect general difficulty in interpreting the clinical significance of the effectiveness of a N_2O-free regimen in preventing PONV.

This meta-analysis overcame these problems by combining results from all relevant reports, by recording each emetic outcome separately and by analysing both the statistical and clinical significance of the effect of a N_2O-free anaesthetic on PONV. Omitting N_2O in general anaesthesia had no effect on the incidence of nausea or on complete emetic control; however, it was followed by a statistically significant reduction in early and late vomiting and the NNT indicated that patients at high risk of vomiting were the most likely to profit from omitting N_2O.

The baseline risk of vomiting is of multifactorial origin. Types of surgery, anaesthetic techniques, sex and age of patients were comparable in subgroups with a low or high baseline risk of vomiting. Even in paediatric strabismus surgery, a well defined subgroup with a recognized high baseline risk of postoperative vomiting, an extraordinarily wide range of vomiting incidence has been reported [50]. This suggests that the baseline risk of vomiting is not simply dependent on a particular type of surgery, anaesthetic or patient but is rather defined by the whole clinical setting.

Interestingly, the risk reduction was not useful as a predictor of the emesis-reducing effect of a N_2O-free anaesthetic. For early vomiting, the combined risk reduction with a N_2O-free anaesthetic was 27% in studies with a low baseline incidence of vomiting. However, the NNT method indicated that almost 60 patients would need to be treated with a N_2O-free anaesthetic in this setting for one to profit. For late vomiting the risk reduction with a N_2O-free anaesthetic in studies with a high baseline risk of vomiting was only slightly higher (35%) but this time only six patients needed to undergo a N_2O-free anaesthetic for one to profit. This proves that the NNT is a useful measure of clinical significance because it takes into account the risk both with and without treatment. This also confirms that the NNT method is helpful in identifying a high-response subgroup of patients who have the most to gain from the treatment [51].

Subgroup analysis can be informative but it is also potentially misleading [52]. To omit such pitfalls, we first described a difference in the magnitude of the emesis-preventing effect of a N_2O-free anaesthetic that is clinically important. Second, if a hypothesis is confirmed in a meta-analysis that excludes data from the study that originally suggested a particular interaction, the inference is stronger. Analysis of the largest trials suggested an inverse relationship between baseline risk of vomiting and NNT to prevent vomiting with a N_2O-free anaesthetic. Exclusion of these studies from the combined analysis confirmed or even accentuated the results of the subgroup analysis. Third, the larger the difference between the effect in a particular subgroup and the overall effect, the more plausible it is that the effect is real. Compared with the combined outcome of all RCT (NNT 12–14 to prevent vomiting) the prevention of vomiting efficiency of a N_2O-free regimen was increased almost three-fold when only the subgroup with a high baseline risk was analysed. When only trials with a low baseline risk were analysed, the overall efficiency of a N_2O-free regimen in decreasing vomiting became three times weaker. Finally, this overview of the relevant literature found an interaction between baseline risk of vomiting and N_2O which was present consistently. It has been suggested that such consistency is the best single index as to whether or not the results of a subgroup analysis should be believed [52].

It has been suggested that omitting N_2O in propofol anaesthesia would be followed by a more pronounced decrease in PONV than omitting N_2O in halogenated anaesthetics [49]. A TIVA with propofol was followed by a statistically significant decrease in vomiting compared with control and the combined NNT to prevent early and late vomiting were lower than the combined data of all RCT. However, the two propofol studies reporting statistically significant improvement in the N_2O-free anaesthetic also reported a high incidence of vomiting in controls, supporting the results of the baseline risk subgroup analysis. Moreover, for early vomiting, the confidence interval of the combined NNT was very wide, indicating that this result has to be interpreted cautiously.

The benefit of a particular intervention has to be balanced against its potential for harm. In the most advantageous clinical situation (i.e. a setting with a high risk of PONV), 20% of treated patients may profit from the emesis-reducing effect of a N_2O-free anaesthetic. Based on data from this meta-analysis the risk of intraoperative awareness is 10 times lower in the same setting. In the least advantageous situation (i.e. a setting with a low risk of PONV), for every patient profiting from a N_2O-free anaesthetic one other would experience intraoperative awareness. The question is then if the result of the meta-analysis is representative, as only seven of 24 RCT reported recall as an outcome. The confidence interval of the NNT indicated that we can be 95% confident that intraoperative awareness does occur between in as many as 4% or in as few as 0.17% of patients undergoing a N_2O-free anaesthetic. In a series of 180 consecutive patients undergoing general anaesthesia without N_2O, none reported recall [53]. In this situation we would be 95% confident that the chance of intraoperative awareness with a N_2O-free anaesthetic is at most 1.7% [54]. The result of Moseley and colleagues [53] is in agreement with the result of our meta-analysis and we have to assume that the NNT point estimate from our calculation (NNT 46) lies close to the "true" value. Conscious awareness with recall produced by a particular anaesthetic technique is major harm and indeed is of major concern both to patients and anaesthetists. It can lead to serious psychological sequelae [55, 56]. Premedication with benzodiazepines does not guarantee absence of recall [27], but even in the presence of N_2O, intraoperative awareness may occur [57].

In conclusion, omitting N_2O from general anaesthetics decreases postoperative vomiting significantly but only if the baseline risk of vomiting is high. Omitting N_2O does not affect nausea or complete control of emesis. There is no evidence that omitting N_2O is more effective in propofol than in halogenated anaesthetics. The clinically important risk of intraoperative awareness with a N_2O-free anaesthetic reduces the usefulness of this method of preventing postoperative vomiting.

Cognitive failures after general anaesthesia for day-case surgery†

Y. TZABAR, A. J. ASBURY AND K. MILLAR

Summary

Patients are normally thought to have recovered from general anaesthesia within a few hours after day-case surgery. Previous recovery studies using objective psychometric tests showed a return to baseline values within this period. Nevertheless, patients are advised about what activities they should not undertake in the subsequent 24 h because it is feared that the residual anaesthetic effects may impair their ability. These studies did not follow patients out of hospital and their relevance to the real world is not known. Using the cognitive failures questionnaire, a standard measure of performance of everyday tasks, 54 patients were asked to report their own performance after general anaesthesia for the 3 days after discharge from hospital: 30 local anaesthetic patients were studied for comparison. The general anaesthesia group reported a highly significant greater incidence of cognitive failures after anaesthesia compared with the local anaesthesia group. This suggests that the residual effects of anaesthesia persist beyond 24 h. (*Br. J. Anaesth.* 1996; **76**: 194–197)

Key words

Anaesthesia, day-case. Psychological responses, postoperative.

When discharged after day-case surgery, patients are usually advised to avoid activities such as driving or operating hazardous machinery for 24 h after anaesthesia because residual effects may impair their cognitive ability and make them more liable to accidents. To estimate such residual effects, psychomotor and cognitive test batteries are often conducted within a few hours of the anaesthetic and show that cognitive performance has returned to preoperative baseline levels within 3–4 h.

It is possible, however, that such studies may underestimate residual impairment in patients because even when suffering severe fatigue or after-effects of sedation, individuals can muster sufficient resources to perform satisfactorily for short periods [1, 2]. There is at least anecdotal support for the idea that patients are impaired for several days after general anaesthesia; patients report forgetfulness or inability to concentrate. It is obviously important to know how recovering patients "perform" not only in hospital but also at home and it is possible that useful insight may be gained from patients' subjective assessment of their state, recorded several days after the event. We used the well-established cognitive failures questionnaire (CFQ) [3] which permits self-assessment of cognitive and psychomotor impairment, to assess day-case patients 3 days after anaesthesia. The CFQ has not been used, to our knowledge, in previous anaesthetic recovery research. However, while there are no existing data that might indicate its specific validity in such circumstances, its use in other patient groups confirms that it provides a reliable and valid measure of impaired cognitive function [4].

The objective of this study was to investigate cognitive function over 3 days after day-case anaesthesia using the CFQ.

Patients and methods

The study was approved by the Ethics Committee of the Victoria Infirmary, Glasgow.

The CFQ is a standardized instrument to collect information on cognitive lapses which occur in everyday life. It has been used to study cognitive failures in groups of healthy individuals and also in patients with physical and psychological problems such as chronic pain, terminal cancer and chronic fatigue syndrome [4]. The lapses usually indicate failure of perception, memory or a misdirected action. Such lapses are often minor but may have serious implications when driving or operating hazardous equipment at work or in the home.

The CFQ consists of 25 questions about lapses or mistakes that commonly occur in everyday life (see appendix). For each question, the respondent rates how frequently the error has occurred over the relevant time period. Each question can score from 0 to 4 so that the maximum score is 100. The higher the CFQ score, the greater the incidence of cognitive failures. The CFQ has the advantage of being easy to administer and provides a retrospective measure of integrated cognitive function over a period of time.

After obtaining informed consent, day-case patients undergoing surgery with general or local anaesthesia were asked to complete the CFQ with respect to the 3 days before admission. Patients receiving sedation (e.g. endoscopies), those aged less

†Presented in part at the Anaesthetic Research Society, Leeds Meeting, March 31–April 1, 1995 (*British Journal of Anaesthesia* 1995; 75: 231P).

than 18 yr, women undergoing termination of pregnancy and patients who were subsequently admitted after operation to the ward were excluded from the study. Patients took home a second CFQ with instructions to complete it 3 days after anaesthesia and return it in a pre-paid envelope. The second CFQ asked about the 3 days after discharge from hospital. Three days was chosen after a pilot study which found no difference between general and local anaesthesia groups at 7 days. This aspect of the methodology is considered further in the discussion.

The general anaesthetic technique was not standardized because the objective of this study was to detect alterations in cognitive function which could be found after general anaesthesia rather than to compare the effects of different agents and techniques. In the majority of cases, however, anaesthesia was induced with propofol, and maintained with a volatile agent, nitrous oxide, and a small dose of opioid. Limited opioids were used in the postoperative period according to local practice, and were not taken home by patients. No patient undergoing a procedure under local anaesthesia was sedated.

For obvious reasons it was impossible to allocate patients randomly to general or local anaesthesia groups. A wide variety of surgical procedures were carried out, including gynaecology, orthopaedic, dental, ENT and general surgery.

Data were analysed using the chi-square test for categorical data. The scores were treated as ordinal data and the Mann–Whitney and Wilcoxon rank tests were used for between-group and within-group hypothesis testing. $P < 0.05$ was considered significant.

Results

Eighty-two general anaesthesia and 39 local anaesthesia patients agreed to take part in the study. Of these, 54 (68 %) and 30 (77 %) returned their second questionnaire and the analysis is based on these samples. Patient data are shown in table 1. The general anaesthesia patients were significantly younger ($P < 0.01$, Mann–Whitney), and significantly more were female ($P < 0.05$, chi-square). This is an inevitable reflection of the work of the day surgery unit which includes a large gynaecology practice.

Pre- and post-anaesthetic CFQ scores for the two groups are shown in table 2. The general anaesthesia group reported significantly more cognitive failures during the 3 days after anaesthesia than during the same period before anaesthesia ($P < 0.01$, Wilcoxon). The local anaesthesia group showed no significant change. Moreover, a between-group analysis confirmed that while the general and local anaesthesia groups did not differ in pre-operative CFQ scores ($P > 0.05$, Mann–Whitney), the post-operative CFQ score in the general anaesthesia group was significantly higher than that in the local anaesthesia group ($P < 0.01$, Mann–Whitney).

Table 1 Patient data for the general (GA) and local anaesthesia (LA) groups

	GA group ($n = 54$)	LA group ($n = 30$)	P
Age (yr)

P (between groups)	ns	< 0.01	

Discussion

The CFQ data indicated that in a 3-day period after discharge, patients who underwent general anaesthesia experienced a significant increase in cognitive failures relative both to preoperative baseline values and to patients who underwent local anaesthesia. An initial conclusion would be that the after-effects of the anaesthetic, or the surgical procedure, continue to exert an adverse effect on cognition after general anaesthesia.

This conclusion would seem consistent with evidence from the few studies which have extended the assessment of cognitive recovery (in hospital) beyond the usual period of a few hours after return of consciousness. For example, *choice reaction time* has been shown to be impaired for 36 h [5] and *digit–symbol substitution* for 2–3 days [6] after general anaesthesia. Unfortunately, those studies which made direct comparisons between general and local anaesthesia recovery profiles are not helpful in the present case because they conducted assessments only in the immediate recovery stage and then at 3 months where, perhaps not surprisingly, no effects were found [7, 8].

There may have been some imprecision in the present assessment of the duration of impairment. Although the pilot study suggested that no impairment was present at 7 days, the sample sizes were rather small ($n = 10$) and therefore of low power. The choice of a 3-day assessment period was therefore somewhat arbitrary. A more extensive study may be required to determine the precise profile and duration of impairment, as judged by the CFQ.

The mechanism of residual impairment has been proposed as the residual effect of anaesthetic drugs on higher brain centres [9] or increased metabolic demands induced by the endocrine response to surgery [10]. While there is some evidence that general anaesthesia is indeed associated with a greater endocrine "stress" response than local anaesthesia, there is no associated evidence of differential cognitive impairment [8].

The fact that the general anaesthesia group reported greater impairment may be difficult to interpret because of the confounding factor of the different surgical procedures experienced compared with the local anaesthesia group. Not surprisingly, the general anaesthesia patients underwent more invasive surgery than the local anaesthesia group, for example laparoscopy compared with carpal tunnel decompression. Moreover, while the effect was statistically significant, it is difficult to judge its clinical significance because there are no appropriate normative data for the CFQ. The between-group difference was therefore suggestive but needs to be interpreted with caution. None the less, it is interesting that the general anaesthesia group did report greater impairment despite their significantly younger age composition.

There are further subjective biases that may affect patient responses even on standardized instruments [11–13]. The CFQ is a retrospective measure and is therefore subject to the vagaries of human memory. This may include not only forgetting incidents of cognitive failure, but also confabulation and misattribution of real incidents to the incorrect time period. For instance, some patients may have memories of profound impairment occurring in the immediate 24-h recovery period which they mistakenly believe and report to have occurred later during the 3-day study period. Such "false memories" can be difficult to assess. Moreover, patients completed the second questionnaire when unsupervised at home and it is possible that their responses were biased by the comments of partners and family on their condition. It is also possible, given the results of studies with other sedative agents, that patients in the general anaesthesia group may have "expected" to suffer impairment and that this expectation biased their responses in a negative way [12].

The fact that the CFQ itself enquires about impairment may bias some patients to respond positively. Given the standardized nature of the CFQ, one could not readily modify it in an attempt to "disguise" its true intent. However, future studies might contrast CFQ responses with performance on objective tests of recovery (reaction time, attention, etc.) whereby unimpaired performance on objective tests allied to subjective impairment on the CFQ might imply some bias in the latter assessment.

The response rates of 68 % and 77 %, respectively, for the general and local anaesthesia groups may detract slightly from the reliability of the conclusions. They may also introduce bias because those patients who had experienced particular impairment may have felt more motivated to return the questionnaire. A future study might consider interviewing all patients in the sample at home so as to ensure the recording of as full range of responses as possible. Another methodological improvement might be the inclusion of a non-operated, matched control group to take account of the fact that the incidence of cognitive failures probably varies from day to day even in the "normal" state.

As a tentative conclusion, the present results indicated that general anaesthesia patients perceived a residual impairment of their cognitive faculties over the 3 days after general anaesthesia. It would be important to extend the present study to include some degree of randomization between general and local anaesthesia in order to ensure equivalence in the procedures undergone. This presents some difficulty as such a study would be limited to operations that could be carried out equally well under both general and local anaesthesia and require that both patient and surgeon would agree to randomization rather than have a free choice. It would also be valuable to examine the degree of correlation between CFQ scores and the more commonly used psychomotor and cognitive test batteries. Recovery research has shown that psychological assessments have much to offer anaesthetic practice and there is considerable virtue in attempting to increase the "ecological validity" [1] of those assessments by demonstrating that their performance profiles are accurate reflections of the patient's state when discharged into the real world.

Appendix

THE COGNITIVE FAILURES QUESTIONNAIRE

The following questions are about minor mistakes which everyone makes from time to time, but some of which happen more often than others. For each question the subject is asked to indicate how often these things have happened in the relevant time period by circling the appropriate number. (From: Broadbent DE, Cooper PF, FitzGerald P, Parkes KR. The cognitive failures questionnaire (CFQ) and its correlates. *British Journal of Clinical Psychology* 1982; 21: 1–16)

Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery

M. RAUCOULES-AIMÉ, Y. LABIB, J. LEVRAUT, P. GASTAUD, C. DOLISI AND D. GRIMAUD

Summary

We conducted a randomized, prospective study to assess the effect of i.v. insulin on blood glucose control, development of ketone bodies and hormonal changes in 60 well-controlled, non-insulin-dependent diabetics (NIDDM) undergoing major surgery. In group A, patients were given only 0.9% saline; in group B, patients were given insulin as a continuous i.v. infusion (1.25 u. h^{-1}); in group C, patients were given insulin 10 u. i.v. boluses every 2 h. Patients in all three groups were given insulin 5 u. when their intraoperative blood glucose concentration increased to greater than 11.1 mmol $litre^{-1}$. Blood glucose concentrations were measured every 15 min, from just before induction of anaesthesia to 2 h after surgery. Plasma lactate, pyruvate, ketone body, C-peptide and counter-regulatory hormone concentrations were also measured. Blood glucose concentrations in the three groups did not differ significantly. There was a mild-to-moderate increase in plasma ketone body concentrations in group A, but without any deleterious consequences. Plasma C-peptide concentrations decreased significantly in groups B and C, especially in patients given bolus injections of insulin. Plasma growth hormone concentrations also increased significantly in group B and C patients. This study indicated that the "no insulin–no glucose" regimen was a simple, effective way to control blood glucose in well-controlled NIDDM patients, provided blood glucose was measured frequently and insulin used appropriately. (*Br. J. Anaesth.* 1996; **76**: 198–202)

Key words

Complications, diabetes. Metabolism, insulin. Metabolism, glucose. Diabetes.

There is some controversy on the metabolic management of patients with non-insulin-dependent diabetes mellitus (NIDDM) undergoing surgery [1–4]. Clearly, poorly controlled NIDDM patients should be given insulin, while well-controlled ones undergoing minor surgery do not require any special treatment [1, 5, 6]. The case for the metabolic management of NIDDM patients undergoing major surgery with insulin is not simple [1, 4]. Insulin may induce hypoglycaemia and metabolic abnormalities [2], complicating the management of anaesthesia. Controlling blood glucose with insulin appears to provide little or no benefit over no-insulin treatment [7]. Some authors therefore propose giving insulin only when blood glucose concentrations exceed 11.1 mmol $litre^{-1}$, assuming there is adequate preoperative control and perioperative blood glucose monitoring [8], while others routinely give NIDDM patients insulin [1]. They point out that, in spite of hyperinsulinaemia, frequently found in these patients, hyperglycaemia, osmotic diuresis, ketosis and acidaemia may occur under stressful conditions.

We therefore conducted a randomized, prospective study to evaluate the effects of i.v. insulin on blood glucose control, ketone body development and hormonal changes in well-controlled NIDDM patients undergoing major surgery.

Patients and methods

We studied 60 NIDDM patients undergoing elective orthopaedic surgery (hip replacement, spinal surgery) or abdominal surgery (cholecystectomy, gastrectomy, bowel resection). The study was approved by the Ethics Committee of the University Hospital Centre and informed consent was obtained from all patients. Inclusion criteria were: fasting plasma blood glucose < 7.9 mmol $litre^{-1}$ and glycosylated haemoglobin (HbA_{1C}) less than 8% [8, 9]. Patients with impaired renal function (creatinine > 120 µmol $litre^{-1}$) or impaired hepatic function (based on routine liver function tests) were excluded from the study. None of the patients had been given insulin previously. Sulphonylurea hypoglycaemic drugs were discontinued the night before surgery, and biguanides 72 h before. All had fasted for 12–14 h before surgery.

Patients were allocated randomly to one of three groups. Group A ($n = 20$) patients were given only 0.9% saline 125 ml h^{-1} ("no insulin–no glucose"). Patients in groups B and C were given a continuous infusion of 5% glucose 6.25 g h^{-1} with i.v. short-acting insulin (Actrapid HM, Novo, France), started just before induction of anaesthesia. In group B ($n = 20$), patients were given insulin as a continuous infusion (1.25 u. h^{-1}) by an electrically driven syringe (40 u./31 ml 0.9% saline (1.25 u. = 1 ml)) [10]; patients in group C ($n = 20$) were given insulin 10 u. by direct i.v. bolus injection every 2 h [11]. Patients in all three groups were anaesthetized only

when blood glucose concentration was 5.5–11.1 mmol litre^{-1}; if the concentration was < 5.5 mmol litre^{-1}, glucose was given; if it was > 11.1 mmol litre^{-1}, additional insulin (5 u.) was given as an i.v. bolus until blood glucose was < 11.1 mmol litre^{-1}. During surgery, all patients were given a bolus injection of insulin 5 u. whenever blood glucose exceeded 11.1 mmol litre^{-1}, with at least 60 min between doses. A second venous cannula was used to infuse other medications or 0.9 % saline for volume expansion (fluids containing glucose and lactate were prohibited).

All patients were premedicated with flunitrazepam 1–2 mg orally. All procedures were performed under general anaesthesia. Anaesthesia was induced with thiopentone 5 mg kg^{-1}, and tracheal intubation was facilitated with vecuronium 0.1 mg kg^{-1}. Fentanyl 2 µg kg^{-1} was used at induction and during anaesthesia in response to hypertension, tachycardia, or both. Anaesthesia was maintained with 0.8–1 % enflurane and 50 % nitrous oxide in oxygen. Neuromuscular block was maintained with vecuronium, which was not antagonized after surgery. Ventilation of the lungs was controlled to maintain end-tidal $P\text{CO}_2$ at 4.8–5.3 kPa.

The study began just before induction and ended 2 h after surgery. Capillary concentrations of glucose were measured every 15 min. Plasma ketone bodies (acetoacetate, β-hydroxybutyrate), lactate, pyruvate, C-peptide and counter-regulatory hormones (catecholamines, cortisol, glucagon, growth hormone) were measured in venous samples (S) taken just before induction (S1), during surgery (S2: 30 min after the beginning of cholecystectomy; 60 min for gastrectomy, bowel resection, hip replacement and spinal surgery), and immediately after completion of surgery and tracheal extubation (S3). Details of the assays have been published previously [10]. The following variables were recorded: capillary glucose concentrations; treatment failure (defined as blood glucose concentration < 3.3 mmol litre^{-1} or > 16.5 mmol litre^{-1}); total amount of insulin and number of additional boluses given; plasma acetoacetate and β-hydroxybutyrate : acetoacetate ratios at S1, S2, S3; plasma lactate, pyruvate concentrations and lactate : pyruvate ratios at S1, S2, S3; plasma C-peptide and counter-regulatory hormone concentrations at S1, S2, S3.

Data were analysed by two-way analysis of variance (ANOVA) for repeated measurements. Student's unpaired two-tailed *t* test was used to compare groups. Comparison of two time points within a group were made using Student's two-tailed *t* test for paired data. The resulting *P* values were adjusted by Bonferroni's method. ANOVA was used to compare the amount of insulin given in both groups and the quantities of fentanyl. β-hydroxybutyrate : acetoacetate and lactate : pyruvate ratios were compared using non-parametric tests. Non-parametric tests were also used to compare plasma growth hormone concentrations. The chi-square test was used for non-continuous variables. Results are expressed as mean (SEM). $P < 0.05$ was considered statistically significant. Statistical analyses were performed using a MacIntosh II computer with the Statview program.

Results

There were no significant differences between the groups in patient data, type or duration of surgery, duration of diabetes or preoperative control of glycaemia, determined by HbA_{1c}, fasting plasma glucose and capillary glucose concentrations measured just before induction of anaesthesia (table 1). The doses of fentanyl given to the three groups were similar (A: 665 (25) µg; B: 602 (25) µg; C: 650 (22) µg). Seven patients had blood glucose concentrations controlled by diet alone (two in group A, three in group B, two in group C). Six patients in group A, six in group B and five in group C were given blood products during surgery (packed red blood cells or plasma).

The distribution of all blood glucose concentrations (expressed as percentiles) measured every

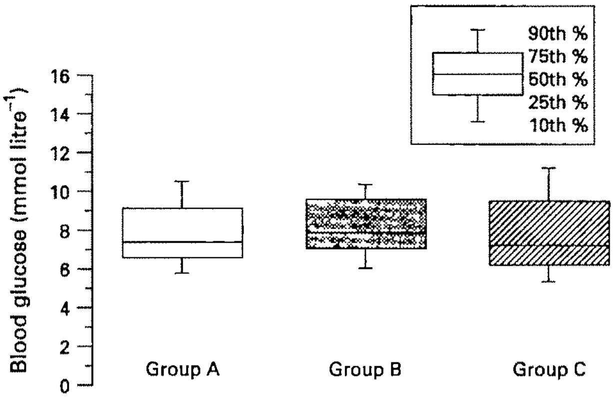

Figure 1 Distribution of blood glucose values measured every 15 min during the study, displayed as percentiles (%), for groups A (no insulin–no glucose), B (continuous infusion) and C (bolus).

Table 1 Patient data, blood glucose concentrations (BGC) just before induction of anaesthesia, haemoglobin A_{1c} (HbA_{1c}) and duration of diabetes in group A (no insulin–no glucose), group B (continuous infusion) and group C (bolus) (number or mean (range or SEM)). No significant differences between groups

	Group A ($n = 20$)	Group B ($n = 20$)	Group C ($n = 20$)
Sex distribution (M/F)	12/8	13/7	13/7
Age (yr)	61.9 (45–81)	64.5 (48–80)	61.1 (41–77)

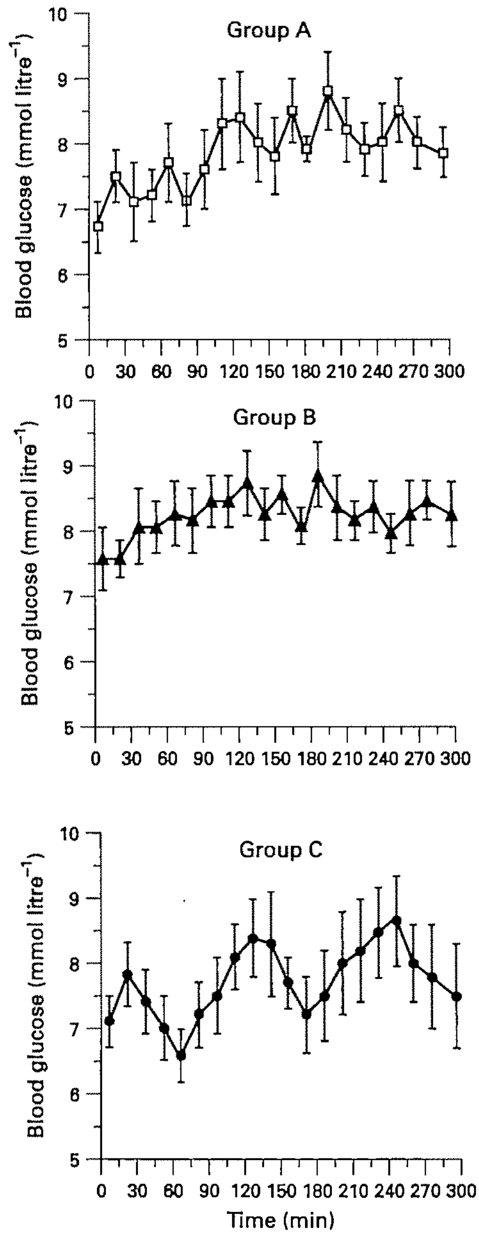

Figure 2 Mean (SEM) blood glucose concentrations measured every 15 min in groups A (no insulin–no glucose), B (continuous infusion) and C (bolus). No significant differences between groups.

15 min during the study in all groups is shown in figure 1. Blood glucose concentrations in the three groups were not significantly different (two-way repeated ANOVA) (fig. 2). Infusion of glucose was increased in three patients (one in group A, two in group B) just before induction of anaesthesia to offset low blood glucose concentrations (< 5.5 mmol litre^{-1}). The number of additional insulin boluses given when intraoperative blood glucose concentrations exceeded 11.1 mmol litre^{-1} was similar in all three groups (table 2). No case of hypoglycaemia (blood glucose < 3.3 mmol litre^{-1}) or hyperglycaemia (blood glucose > 16.5 mmol litre^{-1}) was encountered.

Plasma β-hydroxybutyrate concentration increased just before anaesthesia (S1) and gradually decreased during surgery ($P < 0.05$), except in group A, where concentrations remained increased (S2: 0.63 (0.10–1.19) mmol litre^{-1}; S3: 0.71 (0.12–1.08) mmol litre^{-1}) (table 3). Acetoacetate concentrations did not differ significantly (group A, S2: 0.39 (0.10–0.69) mmol litre^{-1}; S3: 0.45 (0.10–0.72) mmol litre^{-1}) and the β-hydroxybutyrate: acetoacetate ratio did not vary significantly with time. It remained > 1 in group A, but decreased in groups B and C ($P < 0.001$, $P < 0.01$). Plasma lactate and pyruvate concentrations increased significantly ($P < 0.05$ and $P < 0.01$) during surgery, with no differences between groups, although pyruvate concentration increased to a lesser extent in group A. The lactate:pyruvate ratio did not change throughout the study (table 3). There were no major metabolic problems during the postoperative period in any of the three groups.

Plasma C-peptide concentrations differed significantly between the groups ($P < 0.01$) (table 4). The time course of changes in the concentrations were also significantly different ($P < 0.0001$). C-peptide concentrations decreased significantly during surgery in groups B and C (table 4), especially in patients given bolus injections of insulin ($P < 0.001$), while plasma C-peptide concentrations remained stable in group A.

Plasma cortisol and catecholamine concentrations increased similarly during surgery in the three groups (table 4). Plasma glucagon concentrations remained stable. Plasma growth hormone concentrations were significantly different between groups ($P < 0.01$); they increased significantly in groups B and C ($P < 0.05$, $P < 0.01$) and remained constant in group A.

Discussion

The majority of diabetics undergoing surgery in Western countries are non-insulin-dependent. Nevertheless, there is no consensus on the best method of managing blood glucose concentrations of patients with well-controlled NIDDM undergoing major surgery, especially in the use of insulin [1, 5, 8]. The main metabolic complications in diabetics during surgery are hypoglycaemic reactions caused by exogenous insulin, hyperglycaemia, ketosis and acidaemia [8]. This study showed that the control of blood glucose was similar, whether or not patients

were given insulin. The "no insulin–no glucose" patients developed mild-to-moderate concentrations of ketone bodies.

Some authors believe that well-controlled NIDDM patients do not require special treatment before and during surgery [5, 6, 8], and that insulin therapy should be considered only when intraoperative blood glucose concentrations exceed 11.1 mmol litre^{-1}. This value was proposed because the renal threshold for glucose is 10.0–11.1 mmol litre^{-1} in most patients with normal renal function [12]. Osmotic diuresis results in water and electrolyte losses, hyperosmolarity and impaired CNS function if this level is exceeded. The literature also suggests that impaired wound healing and strength, and impaired phagocytic function may occur when plasma glucose concentrations exceed 11.1 mmol litre^{-1} [3, 13, 14]. Intraoperative blood glucose control was good in most patients on the "no insulin–no glucose" regimen in our study. These finding are consistent with those of Fletcher, Langman and Kellock for minor and moderate surgery [15]. Fasting was probably the cause of these stable blood glucose concentrations [16], because glucose given without insulin can result in marked hyperglycaemia [11, 17]. Fasting and a lower insulin:glucagon ratio were also responsible for the accelerated ketogenesis in the "no insulin–no glucose" group. But, because of residual endogenous insulin secretion in our patients, the development of ketone bodies was limited, and without any deleterious consequences. Ketogenesis was similar to that of normal subjects after short-term starvation [16]. Concentrations of lactate and pyruvate in the insulin-treated patients were increased, presumably as a result of insulin inhibiting gluconeogenesis and increased extrahepatic lactate production from glucose [16]. The lactate:pyruvate ratios were within normal limits for venous blood samples and were not affected by insulin administration. Thus, our results suggest that the "no insulin–no glucose" regimen provided sufficient metabolic control during the operative period and might even be preferable as it avoids the risk of hypoglycaemia. The incidence of hypoglycaemia was 5–10 % whatever insulin regimen was used [10]. While our study was relatively short, it is always possible that some metabolic disturbance may occur later, but no major metabolic problem was identified during the postoperative period.

The decrease in plasma C-peptide concentrations in groups B and C probably resulted from negative feedback by exogenous insulin on pancreatic insulin secretion. This decrease was even more significant in the group treated with large bolus doses of insulin. This inhibition develops over a few hours after insulin therapy is initiated in non-surgical situations [18]. The lack of increase in plasma GH in the "no insulin–no glucose" group appears to be surprising, because there is usually a gradual increase in GH during stress, which parallels that of cortisol and takes place a few minutes after induction of anaesthesia [19]. It has been shown that elevated plasma ketone body concentrations decrease the release of GH [20, 21]. The increase in GH concentrations in groups B and C may also result from stimulation of GH release by exogenous insulin [20]. However, this difference in growth hormone concentration did not alter blood glucose. The deleterious effect of increased growth hormone on blood glucose in diabetics is probably not as pronounced as the effect of catecholamines and cortisol [22]. This lack of difference in blood glucose concentration may also be caused by administration of exogenous insulin, which counteracts the effect of growth hormone on glucose metabolism.

Thus this study indicated that the "no insulin–no glucose" regimen was a simple, effective way of controlling blood glucose in well-controlled NIDDM patients, provided that blood glucose was measured frequently and insulin used as appropriate.

Pulmonary uptake of sufentanil during and after constant rate infusion

F. BOER, E. OLOFSEN, J. G. BOVILL, A. G. L. BURM, A. HAK, M. GEERTS AND K. E. WETSELAAR

Summary

We have studied the pulmonary uptake of sufentanil in patients during and after a short infusion of the drug. We studied 10 patients undergoing elective coronary artery bypass surgery during anaesthesia with 0.4–0.8% enflurane, before surgery. Sufentanil 50 μg min^{-1} was given over 10 min by a constant rate infusion. During infusion and for 20 min thereafter, blood samples were obtained from the distal port of the pulmonary artery catheter and from a radial artery catheter. Uptake and release of sufentanil into and from the lungs were examined by mass balance and compartmental analyses. At the end of the infusion a mean of 48.9 (SD 18.6)% of the dose was retained in the lungs, and 20 min after infusion retention was 18.4 (22.4)%. Smokers had significantly higher pulmonary retention of sufentanil. The pulmonary volume of distribution of sufentanil, estimated from the two-compartment model, was 20.9 (7.7) litre. We conclude that pulmonary uptake of sufentanil is significant, if the drug is given as an infusion. (*Br. J. Anaesth.* 1996; **76**: 203–208)

Key words

Analgesics opioid, sufentanil. Lung, metabolic function. Pharmacokinetics, sulfentanil. Analgesic techniques, infusion.

Sufentanil, a synthetic opioid, undergoes significant first-pass pulmonary uptake after i.v. bolus injection. In cardiothoracic patients, first-pass retention of sufentanil is approximately 60%, considerably higher than that of alfentanil (10%) and morphine (7%) [1]. Pulmonary uptake and release *in vivo* are studied usually with a double-indicator dilution technique, because this requires only arterial blood samples. However, the technique can measure extraction and retention in the lungs only before recirculation of the indicator occurs. Studies of pulmonary uptake and release beyond the first-pass period require both pulmonary arterial and arterial blood sampling. Uptake and release can then be examined using mass balance principles [2].

The mass balance of a drug over an organ is the time integral of organ blood flow times the arterio-venous concentration difference. If flow or concentration, or both, change rapidly, frequent measurement of blood flow and frequent blood sampling are required to obtain accurate results. Mass balance principles can be applied to the study of pulmonary uptake in patients, as pulmonary blood flow can be measured. However, the frequency of manual determination of cardiac output so far has limited the accuracy of mass balance analysis. Recently, a semi-continuous (thermodilution) cardiac output measurement technique has become available, which allows automated and frequent cardiac output measurement [3, 4]; in cardiac surgical patients, this has a mean relative error of 0.8%, an SD of the relative error of 8% and a regression coefficient of 0.87 compared with the bolus thermodilution technique [5, 6]. This technique, in combination with high frequency, automated blood sampling, should allow *in vivo* determination of pulmonary uptake using mass balance analysis.

The aim of our study was to investigate pulmonary uptake and release of sufentanil during and after a short (10 min) constant rate infusion of the drug, using a mass balance technique. Results of the mass balance analysis were compared with those obtained from a physiological compartmental analysis of pulmonary and radial arterial concentrations.

Patients and methods

The study was approved by the local medical Ethics Committee and all patients gave informed consent. We studied 10 patients undergoing elective aorto-coronary bypass surgery. Patients with unstable angina pectoris, poor left ventricular function (defined as an ejection fraction > 0.5, left ventricular end-diastolic pressure < 12 mm Hg or good regional left ventricular wall movement), valvular abnormalities or pulmonary disease were excluded.

Premedication comprised lorazepam 3–5 mg orally, 90 min before arrival in the operating theatre. Patients who were receiving β-adrenoceptor blocking drugs, calcium entry blocking drugs and nitrates continued on these medications until the morning of surgery. In the operating theatre ECG electrodes were attached and cannulae inserted into a peripheral

vein and a radial artery. After induction of anaesthesia, a pulmonary artery catheter was inserted via an internal jugular vein. Before and during induction of anaesthesia, Gelofusin 500 ml was infused to reduce the effect of administration of sufentanil on haemodynamic stability. The peripheral infusion cannula was then maintained patent by a slowly running infusion of 2.5 %–0.45 % glucose–saline until the experiment started. The total volume of glucose–saline administered to individual patients varied between 100 and 300 ml.

Anaesthesia was induced with etomidate 0.3 mg kg^{-1} and alfentanil 30 μg kg^{-1}. Pancuronium 100 μg kg^{-1} was given for neuromuscular block. Anaesthesia was maintained with enflurane with an inspired concentration of 0.6–1.2 %. After intubation of the trachea, the lungs of the patients were ventilated with an oxygen in air mixture ($F\text{I}_{O_2} = 0.5$) by intermittent positive pressure ventilation at a frequency of 12 b.p.m. Minute volume was adjusted to maintain an end-expiratory carbon dioxide concentration of 4.5–5 %. Arterial oxygen and carbon dioxide tensions were measured in arterial blood samples obtained at the start and the end of the 30-min study.

After induction of anaesthesia and placement of the pulmonary artery catheter, when the condition of the patient was stable, the experiment was started. The condition of the patient was considered stable when anaesthesia was adequate, systolic arterial pressure was 100 mm Hg or more, cardiac index was more than 2.1 litre min^{-1} m^{-2} and $F\text{E}'_{CO_2}$ was 4.5–5 %. Sufentanil (Sufenta Forte) 50 μg ml^{-1} was infused at a rate of 1 ml min^{-1} via a peripheral i.v. catheter for 10 min, using a syringe pump (Ohmeda 9000, Strector, UK). The volume infused during the 10-min infusion period was noted. Samples were obtained from the pulmonary artery via the distal port of the pulmonary artery catheter and from the radial artery via the radial artery catheter. Blood was sampled with the aid of a specially constructed, computer-controlled syringe pump and fraction collector. The sample size was equal to the deadspace in the catheter and extension lines to the sample pump and samples were withdrawn over 8 s. Samples were obtained at high frequency, 1 per 10 s, at the start and end of the infusion and at lower frequencies at other time. Sampling was continued until 20 min after the end of the infusion. Both the infusion and sampling were controlled by computer (Atari Portfolio, Okasaki, Japan), interfaced to the syringe pump and the sampling machine via a serial RS232 communication channel.

Cardiac output was measured continuously with the aid of a pulmonary artery catheter (Intellicath, Baxter-Edwards) connected to the cardiac output computer (Vigilance, Baxter Healthcare Corporation). The cardiac output computer gives the mean cardiac output over the previous 3–4 min, depending on the signal-to-noise ratio, and is updated every 45 s. Measurement of cardiac output, arterial pressure, electrocardiogram, function of the infusion pump and of the sampling pump were logged with a data acquisition system (model PS1600, 3T Twente Technology Transfer, Enschede, The Netherlands).

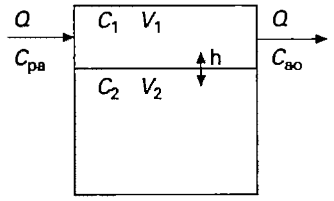

Figure 1 Two-compartment model used to described pulmonary retention of sufentanil. C_{pa} and C_{ao} = concentrations in the pulmonary artery and aorta, respectively, Q = blood flow through the lungs, V_1 and V_2 = volumes of the first and second compartments, C_1 and C_2 = concentrations in the first and second compartments, h = equilibration constant.

Whole blood samples were stored at −20 °C until assay for sufentanil with a highly specific radioimmunoassay [1]. The detection limit was 0.4 ng ml^{-1}, and the coefficients of variation of spiked concentrations of 40 and 100 ng ml^{-1} were 4.5 % and 4.2 %, respectively.

CALCULATIONS

Mass balance analysis

Calculation of mass balance analysis was performed as described by Upton and co-workers [2]. For each sampling time the next flux of sufentanil into or out of the lungs, $J_{net,t}$ was calculated as:

$$J_{net,t} = Q_t(C_{pa,t} - C_{ra,t})$$

where Q = cardiac output (ml s^{-1}), C_{pa} = pulmonary arterial sufentanil concentration and C_{ra} = arterial sufentanil concentration. Subsequently, the net mass balance ($M_{net,t}$) of sufentanil at each sampling time was calculated by integration of the flux $J_{net,t}$:

$$M_{net,t} = \int_0^t J_{net,u}\,du$$

where u = a dummy variable. The integral was approximated using the trapezoidal rule. The percentage of the administered dose of sufentanil which was retained in the lungs at the end of the infusion (t = 600 s) and at the end of the experiment (t = 1800) was calculated as:

$$\text{Retention}_t = \frac{M_{net,t}}{\text{dose}} 100\,\%$$

where the dose was calculated from the infused volume and the concentration of sufentanil in the infusion.

Compartmental analysis

A physiologically based, non-eliminating, membrane-limited, two-compartment model (see for example Gerlowski and Jain [7]), was fitted to the arterial sufentanil concentrations. This model (fig. 1) consists of two-compartments (with volumes V_1 and V_2) in which complete mixing of the drug is assumed to take place. The passive transfer from one compartment to the other is described by a mass transfer coefficient h. Drug transport to V_1 is cardiac output, Q, times the concentration in the pulmonary artery. Transport from the lungs to the effluent blood (left atrium, aorta and the side branches of the aorta) is cardiac output times the concentration in V_1. The change in concentration of the drug (C_1, C_2) in the two compartments is described by the following equations:

$$V_1\frac{\mathrm{d}C_1}{\mathrm{d}t} = Q_t(C_{\mathrm{pa},t} - C_{1,t}) - h(C_1, t - C_{2,t})$$

$$V_2\frac{\mathrm{d}c_2}{\mathrm{d}t} = h(C_{1,t} - C_{2,t})$$

$$C_{\mathrm{ra},t} = AC_{1,t}$$

where A = a proportionality constant, as this significantly improved the fits. This proportionality constant theoretically has a value of 1. However, when drug is lost in the pulmonary circulation (by excretion or elimination), the proportional constant becomes less than 1. The arterial (pulmonary venous) concentrations were predicted by solving the differential equations using Euler's method with linear interpolation of $C_{\mathrm{pa},t}$, $C_{\mathrm{ra},t}$ and Q_t such that the time steps were 1 s. An unweighted iterative non-linear regression technique was used to estimate the model variables V_1, V_2, h and A. If cardiac output is taken as constant, the variables can be transformed to those describing a classical compartmental model. These variables were calculated as $k_{12} = h/V_1$, $k_{21} = h/V_2$ and $k_{10} = Q/V_1$. Cardiac output used for this calculation was the mean cardiac output of the study period.

STATISTICS

Haemodynamic data and arterial blood-gas analyses were analysed by repeated measures analysis of variance, followed by Newman–Keul's multiple range tests when significant differences were observed in the analysis of variance. Unpaired t test analysis was used to compare retention of sufentanil between smokers and non-smokers. $P < 0.05$ was considered statistically significant.

Results

Patient data are presented in table 1. Most of the patients received β adrenoceptor blocking agents and four of the 10 patients were smokers. Haemodynamic data and blood-gas values of the samples obtained during the experiment are given in table 2. Administration of sufentanil significantly decreased heart rate and mean arterial pressure by the end of infusion. At the end of the experiment mean arterial pressure returned to values close to those at the start of the sufentanil infusion, while cardiac output was significantly lower by that time. Blood-gas values did not change significantly during the study.

Smokers	4/10

Infusion of sufentanil resulted in a rapid increase in pulmonary arterial concentrations to a plateau and systemic arterial concentrations slowly increased but never reached pulmonary arterial concentrations (fig. 2). After stopping the infusion of sufentanil, pulmonary arterial concentrations decreased rapidly to values below those of systemic arterial concentrations. Both pulmonary arterial and systemic arterial concentrations decreased slowly during the 20 min after infusion.

Net flux of sufentanil to the lungs, J_{net}, was considerable in all patients during the infusion. Figure 3 shows the individual J_{net} time curves for all patients (upper panel) and the mean J_{net} time plot of the 10 patients (lower). There were considerable differences between patients during infusion of sufentanil, and these differences appeared to be smaller after stopping the infusion of sufentanil. During the infusion, J_{net} increased to a peak 3–4 min after starting the infusion and then decreased gradually. This gradual decrease in J_{net} indicates partitioning to the lungs when lung tissue concentrations increase. At the end of sufentanil infusion, net flux changed from a positive to a negative value, indicating release of sufentanil from the lungs.

Mass balance analysis of pulmonary arterial and radial arterial sufentanil concentrations showed significant uptake of sufentanil in the lungs. Figure 4 gives the individual mass balance curves (upper panel) and the mean mass balance curves of the 10 patients (lower panel). At the end of infusion, 48.9 (18.6) % of the administered dose of sufentanil was retained in the lungs. At the end of the experiment, 20 min after stopping the sufentanil infusion, 18.4 (22.8) % of the administered dose were retained in the lungs. Smokers had significantly higher pulmonary retention of sufentanil. At the end of infusion, pulmonary retention of sufentanil was 64.6 (11.9) % in smokers and 38.5 (14.4) % in non-smokers. This difference was statistically significant ($P = 0.0017$). At the end of the study, pulmonary retention had decreased to 34.9 (21.3) % in smokers and 7.4 (17.3) % in non-smokers. This difference was no longer significant ($P = 0.054$). Smokers and non-smokers were similar with regard to preoperative medication. There were no differences between those patients receiving β blocking agents and those who did not receive these drugs before operation (7 *vs* 3).

An example of the predicted arterial concentration–time curve from the physiologically based, two-compartmental model analysis is given in figure 5 together with the measured concentrations. The results of the compartmental analysis of pulmonary uptake are given in table 3 for each patient. The proportionality factor A was very close to 1, suggesting that sufentanil was not lost in the pulmonary circulation. There was no difference in any of the model variables between smokers and non-smokers.

Table 2 Haemodynamic data and arterial blood-gas values during and after a 10-min infusion of sufentanil at a rate of 50 µg min^{-1} (mean (SD)). * Significant difference from the start of the infusion ($P < 0.05$)

Discussion

We have shown that at the end of a 10-min infusion of sufentanil, almost 50 % of the administered dose was retained in the lungs. After stopping the infusion, sufentanil disappeared slowly from the lungs, so that 20 min after infusion, 18.6 % of the administered dose was retained in the lungs. Smokers demonstrated higher pulmonary retention at the end of infusion. The mean estimated total volume of distribution of sufentanil was 20.9 litre.

Our findings are comparable with those of Taeger and co-workers [8]. They studied pulmonary retention after i.v. bolus injection of fentanyl and alfentanil mixed with indocyanine green. First-pass retention was examined with a double-indicator dilution technique. After the first-pass period, a mass balance technique was used and both arterial and pulmonary arterial samples were obtained. For calculation of the mass balance, they assumed that the amount of fentanyl remaining after first-pass, calculated as the product of first-pass retention and dose administered, can be taken as the initial amount in the lungs that can be used for the mass balance calculation. The first-pass retention of a bolus of fentanyl was 43–87 % and that of alfentanil 36–80 %. Disappearance of fentanyl from the lungs could be described by a biexponential function with half-lives of 0.22 and 5.78 min.

Alfentanil kinetics could not be studied adequately. As no pulmonary arterial samples were obtained

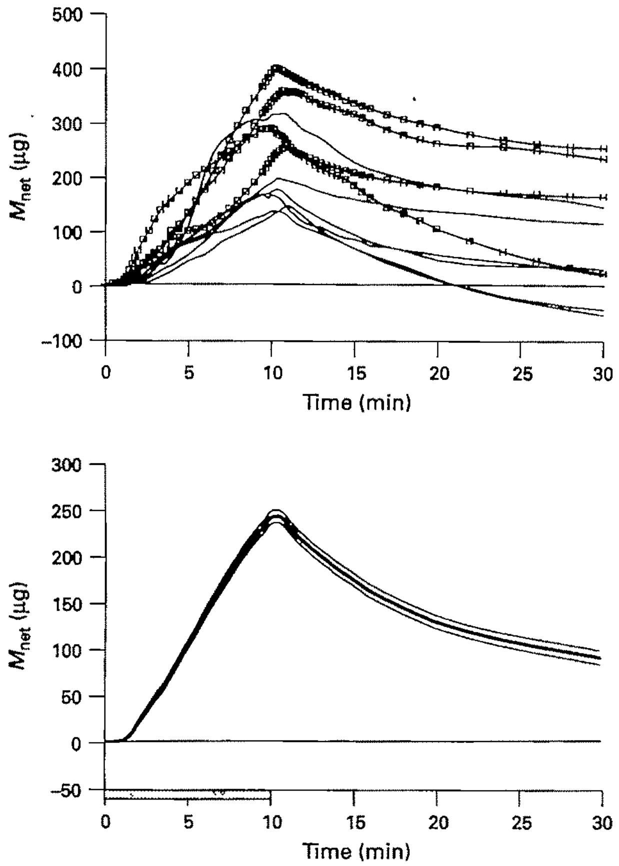

Figure 4 Individual pulmonary sufentanil mass balance (M_{net}) time curves (top), and mean (thick line) and 95 % confidence interval of the mean (thin lines) of the pulmonary sufentanil M_{net} time curve (bottom) for the 10 patients during and after a 10-min infusion of sufentanil at a rate of 50 μg min^{-1} (indicated by the bar). □ = Curves of smokers.

in the first-pass period, considerable recirculation of drug could have occurred before starting pulmonary arterial sampling for the mass balance technique. Cardiac output measurement was infrequent, and the exact timing was not given. We have used a semi-continuous automated thermodilution method, based on system identification analysis [3, 4]. The measurement is semi-continuous, as flow is measured over an epoch period of 45 s and the value presented is the mean of four measurements (i.e. over the last 3 min). Therefore, rapid changes in cardiac output are not observed fast enough to allow correct calculation of the mass balance. However, the changes in blood flow encountered in this study were small as cardiac output decreased gradually to 86 % of initial values over 30 min. Therefore, we feel that the semi-continuous method adequately reflected actual flow.

Mass balance calculation is based on the law of conservation of matter. Mass balance analysis can be applied to the uptake of drugs in an organ or region, if total blood flow feeding that region is known or if flow does not change significantly during the study [2]. Mass balance principles have been used, for instance, to measure uptake and elution of lignocaine and procainamide in the hindquarters of sheep [9]. Use of mass balance principles, however, can be applied only when clear arteriovenous differences are observed. When arteriovenous differences are small compared with the drug assay variability, application of mass balance may yield erroneous results. We have tried to use this method to describe pulmonary retention of alfentanil in a similar patient group. Arteriovenous differences were too small to allow mass balance calculations, because pulmonary retention of alfentanil is small.

The mass balance technique is a model-free method for describing the uptake and release of drug in an organ as a whole. The observed uptake depends on drug characteristics, the method of administration of the drug and the characteristics of the organ or region studied. Because the retention curve depends on the drug input function, the results can only be extrapolated with caution. We have, therefore, also used a non-eliminating, membrane-limited model to describe the pulmonary pharmacokinetics of sufentanil. This model was used assuming that uptake in the lungs is linear with respect to the concentration in the pulmonary artery and that within the flow ranges encountered in this study uptake was not flow-limited. Adding a term for non-linear binding in the model did not improve the prediction of the radial artery concentration curve in these patients, suggesting that binding was linear in our patients. In another study, however, we have shown that first-pass retention of a sufentanil bolus, measured with a double-dilution indication technique, decreased when the background concentration of sufentanil increased [10]. During this study background concentrations of sufentanil increased from 2.8 to 6.9 and 15.9 ng ml^{-1}. First-pass retention of a sufentanil bolus dose was 68 %, 65 % and 60 %, respectively, and retention differed significantly between the lowest and highest background concentrations. The arterial background concentrations in that study were similar to the arterial concentrations encountered in the present study. Possibly sufentanil retention in that study was decreased because sufentanil was given as a bolus. This may have resulted in much higher pulmonary arterial concentrations that those encountered in the present study where sufentanil was given by constant rate infusion.

Table 3 Variables of the physiological based pharmacokinetic model, total volume of distribution and the variables of the system dynamics analysis derived from this model

Patient No.	V_1 (litre)	h (min^{-1})	V_2 (litre)	k_{12} (min^{-1})	k_{21} (min^{-1})	A	$V\mathrm{d}$ (litre)

Pulmonary retention of sufentanil at the end of the infusion calculated from the mass balance was higher in smokers. This increased retention did not result in differences in the variables of the pharmacokinetic model used in this study. The reason for the increased retention is unknown. Cigarette smoking is known to significantly change the metabolism of both endogenous and exogenous compounds [11, 12]. However, sufentanil probably undergoes no pulmonary metabolism, as the proportionality constant A of the model was approximately 1. The increased retention can be explained possibly by the increased lipid content in the lungs of smokers. Cigarette smokers are known to have an increased number of alveolar macrophages [13], and these macrophages have an increased lipid content with lipid inclusions, increased lysosomal volume density and secondary lysosomes [14, 15]. It is assumed that the binding of the weak bases to lung tissue may be attributable to a combination of accumulation in membranes and lysosomal trapping [16]. Thus the increase in pulmonary sufentanil retention in smokers might be attributable to an increased binding capacity of the lungs. Compartment analysis did not reveal differences between smokers and non-smokers. Possibly one of the variables V_1, V_2, h or A did not contain enough information on pulmonary retention after a 10-min infusion. The proportionality constant of the model approached unity indicating that no sufentanil was lost in the pulmonary circulation.

Does pre-incisional thoracic extradural block combined with diclofenac reduce postoperative pain after abdominal hysterectomy?

A. ESPINET, D. J. HENDERSON, K. A. FACCENDA AND L. M. M. MORRISON

Summary

In a double-blind, randomized study, we investigated 40 patients undergoing abdominal hysterectomy; patients received 0.5% plain bupivacaine 20 ml via a low thoracic extradural catheter and a diclofenac suppository (100 mg), either 30 min before incision (group 1) or 30 min after incision (group 2). All patients received a standard general anaesthetic and no opioid was used before or during operation. Postoperative analgesic requirements were measured using a patient-controlled analgesia (PCA) system. Pain was assessed using a visual analogue scale (VAS) and a verbal pain score (VPS) on movement up to 48 h after operation. There was no significant difference in the time to first request for morphine but consumption of morphine was significantly greater in group 1 at all times except 24 h. There were no significant differences in VAS and VPS pain scores, although both scores were consistently higher in group 1. Patient satisfaction with the quality of analgesia, at 24 h, demonstrated no significant difference between the two groups. The combination of extradural block and diclofenac suppository given before operation did not appear to produce a clinically effective pre-emptive analgesic effect. (*Br. J. Anaesth.* 1996; **76**: 209–213)

Key words

Anaesthetic techniques, extradural. Analgesia, pre-emptive. Pain, postoperative. Surgery, gynaecological.

Recent developments in the field of neurophysiology have led to greater understanding of the pathophysiology of acute pain and wider acceptance of the concept of neuroplasticity. The evidence for this concept relies largely on laboratory studies [1, 2] which have demonstrated that peripheral tissue injury may induce long lasting changes in the central nervous system and a state of hyperexcitability (CNS "wind up"). Further stimuli are then thought to potentiate these neural impulses and so generate or intensify pain [3]. Studies with animals have shown that noxious stimulus-induced neuroplasticity can be reduced or prevented (i.e. pre-empted) by pre-injury neural block with local anaesthesia [4, 5], or by administration of opioids i.v. [2] or intrathecally [6]. In addition to this central mechanism of pain production, peripheral sensitization may occur with tissue trauma and lead to pain [7]. Injury may sensitize nociceptors and cause primary hyperalgesia at the site of injury and secondary hyperalgesia in the undamaged tissue surrounding the injury. The mechanisms for this may include release of multiple inflammatory mediators, and other chemicals liberated by, or in reaction to, tissue damage [8, 9]. In order to influence this peripheral pathway, some researchers have used preoperative non-steroidal anti-inflammatory agents (NSAID) and have reported a reduction in postoperative pain [10, 11]. Taken together, these studies would suggest that the use of a combined technique such as local anaesthetic administered centrally and an anti-inflammatory drug (NSAID) peripherally, may reduce postoperative pain and analgesic requirements.

The aim of our study was to evaluate the efficacy of pre-emptive analgesia by combining NSAID and extradural block with local anaesthesia given either before or after surgical incision. Our hypothesis was that if we pre-empted both the central and peripheral sensitization of the nervous system, then patients receiving the pre-incisional analgesic combination would report a lower pain intensity and consume smaller quantities of analgesics after operation, than a similar group given the same combination after incision.

Patients and methods

Over a 6-month period, we studied 40 women, aged 30–60 yr, ASA I or II, undergoing elective abdominal hysterectomy, after obtaining informed consent and approval of the local Ethics Committee. Patients were excluded if there was any history or evidence of back pain, or other chronic pain condition, any contraindication to the use of extradural block, bupivacaine or halothane, regular intake of analgesic drugs, morbid obesity or a psychiatric history.

All patients were premedicated with temazepam 10–20 mg, 60–90 min before operation. Before induction of general anaesthesia, a low thoracic

extradural catheter (T9–12) was sited by one of the authors in a standard manner, using an 18-gauge Tuohy needle. The catheter was flushed with normal saline. No test dose of local anaesthetic was given. The 40 patients were allocated randomly using a numbers table to one of two equal groups. Group 1 received 0.5 % plain bupivacaine 20 ml as a "single shot" and a suppository of diclofenac 100 mg, 30 min before incision. Group 2 received 0.5 % plain bupivacaine 20 ml, 30 min after surgical incision and the diclofenac suppository immediately after surgery. Bupivacaine was administered in a standard manner while observing for signs of toxicity. Adequacy of analgesia (to at least the T10 dermatomal level bilaterally) was assessed with ethyl chloride spray to confirm the height of the block, either before commencement of general anaesthesia (group 1) or on awakening at the end of operation (group 2). Any patient with an inadequate block (i.e. not pain free) was eliminated from the study (one patient from each group). General anaesthesia was induced with a sleep dose of propofol, and neuromuscular block was produced with atracurium. The trachea was intubated and the lungs ventilated with oxygen–air and halothane 1.0–1.5 MAC in order to maintain anaesthesia. The end-tidal carbon dioxide partial pressure was maintained within the normal range (4.5–5.5 kPa). Neuromuscular block was monitored with a peripheral nerve stimulator, and increments of atracurium given as indicated. At the end of the operation residual neuromuscular blockade was antagonized with neostigmine 2.5 mg and atropine 1.2 mg and this time was taken as time "0". Assessment of postoperative pain on movement (from supine to sitting), was made at 2, 4, 6, 12, 24 and 48 h using a 10-cm visual analogue scale (VAS) (0 = no pain, 10 = worst pain imaginable).

A simple four-point verbal pain score (VPS) was also used (0 = no pain at rest or movement, 1 = no pain at rest, slight pain on movement; 2 = intermittent pain at rest, moderate pain on movement; 3 = continuous pain at rest, severe pain on movement). These assessments were made by an independent observer who was blinded to the timing of the extradural block. Postoperative analgesic requirements were measured using a patient-controlled analgesia (PCA) system (Graseby 3300). This was programmed to deliver a 1-mg bolus of morphine with a 5-min lockout and no background infusion. PCA morphine was used for a maximum period of 24 h, after which the patient received diclofenac suppositories or oral codydramol on request. Patient satisfaction with the quality of the analgesia was assessed at 24 h as one of five responses: 1 = very dissatisfied, 2 = dissatisfied, 3 = satisfied, 4 = happy and 5 = very happy.

STATISTICAL ANALYSIS

Before the start of the study, we estimated the sample size required to test the hypothesis that postoperative pain would be less in group 1 than in group 2. Based on previous research at our institution using the same surgical population and the same outcome measure (i.e. VAS for postoperative pain), estimates of the effect size and variance were used to calculate the sample size ($n = 20$ per group) required to give the study a power of 0.9 (and a type 1 error rate of 0.05). The cumulative morphine dose, VAS and VPS pain scores were compared between the two groups at the designated times using the Mann–Whitney test with Bonferroni's type 1 error rate correction for multiple tests of significance. Data are presented as median (quartiles or range). $P < 0.05$ was considered statistically significant for all tests.

Results

Both groups were similar in age, weight and height (table 1). In both groups the duration of surgery was less than 60 min.

The time from the end of surgery to first use of morphine did not differ significantly between the pre-incision (median time 120 (range 30–600) min) and post-incision (120 (60–420) min groups. Morphine consumption was consistently greater in group

1 than in group 2 and this was significant ($P < 0.05$) at all times, except 24 h (table 2). The patients were followed-up for 48 h after surgery and there was no difference in time to discontinuation of the PCA pump or in subsequent analgesic requirements (diclofenac and codydramol), between the two groups.

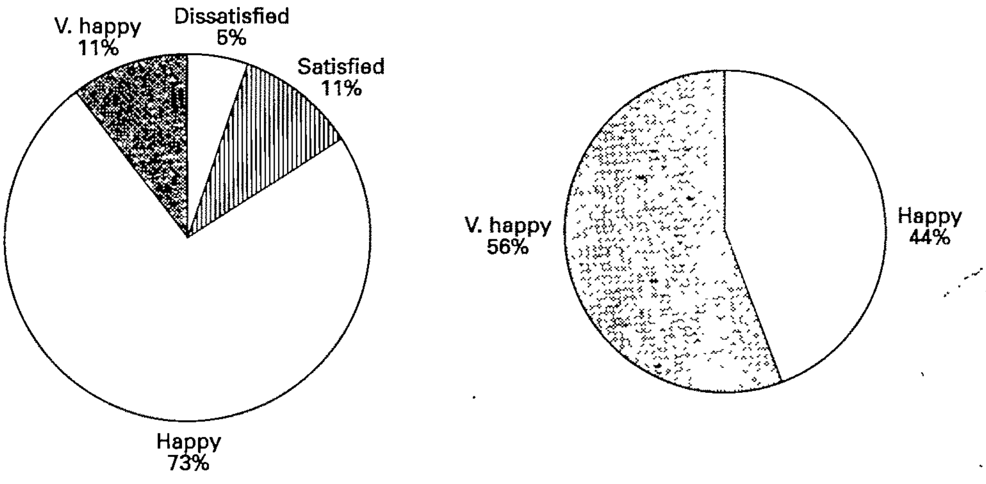
There were no statistically significant differences in VAS and VPS pain scores (figs 1, 2). Patient satisfaction, assessed at 24 h, revealed no significant difference between the two groups (group 1, median score 4 (happy); group 2, median score 5 (very happy)) (fig. 3).

Discussion

Our study failed to show any clinical benefit either in terms of postoperative pain, analgesic requirements or overall patient satisfaction in the group of patients receiving extradural block and diclofenac suppository before, compared with after, surgical incision. A trend was observed in group 1 towards higher postoperative pain scores, higher morphine consumption and lower overall patient satisfaction, suggesting that other factors are important in the pathophysiology of pain after the extensive trauma of major surgery, which may not be applicable in the experimental situation.

Other centres investigating the possible clinical role of pre-emptive analgesia have confirmed our findings. Orntoft and colleagues [12], in a well-controlled, double-blind study, compared pre- and postoperative tonsillar infiltration with bupivacaine and found no beneficial pre-emptive analgesic effect from preoperative infiltration. Pryle and colleagues [13] performed a lumbar extradural block before or after incision to women undergoing abdominal hysterectomy or myomectomy. They failed to demonstrate any pre-emptive benefit on postoperative pain. However, their results may be criticized because both groups received opioid premedication and nitrous oxide was used. Dierking and co-workers [14], using an inguinal field block before or after hernia repair, were unable to demonstrate any difference in either immediate or late postoperative pain. Unfortunately, both groups were given alfentanil i.v. at induction and again during the procedure, and this may have influenced the outcome. Dahl and colleagues [15] studied the effect of continuous extradural analgesia (with bupivacaine and morphine) given before and after major abdominal surgery. They found no significant differences between the two groups in terms of pain scores and analgesic requirements. Again, their results may have been influenced by the fact that in both groups a test dose of bupivacaine was given to confirm correct placement of the catheter, i.v. fentanyl was given at induction and nitrous oxide was used for maintenance of anaesthesia.

Many of the studies which have claimed support for the concept of pre-emptive analgesia have also been flawed because they were either poorly designed [16], retrospective [17], uncontrolled [18, 19] or, when repeated, failed to produce similar results [12, 20]. Pre-emptive analgesic effects have been demonstrated with the use of preoperative and intra-operative opioids (i.v. [6, 21], i.m. [18] and extradural [22]), local anaesthetic test doses [23],



Group 1 ($n = 19$) Group 2 ($n = 18$)

Figure 3 Patient satisfaction 24 h after operation in both groups.

and with the use of nitrous oxide [24]. We designed our study in order to avoid these confounding factors.

The concept of pre-emptive analgesia is an attractive one because, if proved in the clinical setting, it may protect patients from the deleterious effects of surgical incision and other noxious perioperative events long after the operation has been performed. Taken further, the notion of painless surgery presents as a distinct possibility. Clear clinical evidence for pre-emptive analgesia however, has yet to be established, despite what appears to be convincing experimental evidence [1, 2, 4, 5, 25]. Much of the initial work supporting this concept of "pain prevention" originates from animal studies [1, 26], which have demonstrated that under specific conditions in the experimental model, noxious impulses generated by localized peripheral tissue trauma can lead to sensitization of the central nervous system (CNS) and enhancement of painful stimuli thereafter. Preventing these impulses from reaching the CNS can significantly reduce the post-injury hypersensitivity to pain. The exact mechanism for this "wind-up" phenomenon awaits further elucidation, but recent evidence suggests that C-fibre excitatory amino acids and neuropeptides are involved [26]. These may be operating through activation of *N*-methyl-D-aspartate (NMDA) receptors [27] in the short term, but other molecular changes and new gene expression [28, 29] may also play a role in the longer term hyperaesthesia and allodynia.

In the clinical environment, however, other factors may be involved in the production of postoperative pain. For example, surgical trauma differs from the stimuli used in experimental models, in that the afferent input to the CNS during surgery may be extensive, involving mixed cutaneous, muscular and visceral components. The degree of surgical trauma and the site of operation are also important in influencing the amount of nociceptive input. Kehlet's work [30] has shown that complete block of these noxious stimuli during surgery is difficult, unless an extensive extradural block from T4 to S5 is obtained. In addition, persistent inflammation and hyperalgesia at the wound site [14] may generate C-fibre activity well into the postoperative period. In some instances, the magnitude of the injury sustained by the tissues may be comparable with that occurring in the experimental situation. If so, the pre-emptive interventions used are able to produce the dramatic differences between groups of patients reported [31, 32], as has been demonstrated in the animal model. These factors may in part be responsible for the conflicting results of the many clinical studies reported.

Influence of oral clonidine on the ventilatory response to acute and sustained isocapnic hypoxia in human males†

I. T. FOO, P. M. WARREN AND G. B. DRUMMOND

Summary

Animal studies suggest that α_2 agonists inhibit the chemoreceptor response to hypoxia. We have examined the effect of oral clonidine on the ventilatory response to sustained, isocapnic hypoxia (Sp_{O_2} 79.7% (SD 1.1 %) for 20 min) in eight male subjects. The hypoxic ventilatory response was measured before and after both clonidine and placebo. Clonidine had no significant effect on baseline ventilation or gas exchange. After clonidine, the acute hypoxic response (AHR) (mean 5.81 (95% confidence limits 1.94, 9.68) litre min^{-1}) was significantly less than control (10.40 (5.97, 14.83) litre min^{-1}) and hypoxic ventilatory decline (HVD) (3.42(2.35, 4.49) litre min^{-1}) was also significantly less than control (6.49(3.92, 9.06) litre min^{-1}) ($P < 0.05$). After placebo, AHR was similar to control but HVD was significantly larger (6.82(5.28, 8.36) litre min^{-1}) than control (4.79(3.03, 6.55) litre min^{-1}) ($P < 0.05$). Thus clonidine reduced both AHR and HVD but the absolute level of ventilation at the end of hypoxia was unchanged. (*Br. J. Anaesth.* 1996; **76**: 214–220)

Key words

Hypoxia. Ventilation, hypoxic response. Pharmacology, clonidine. Sympathetic nervous system, clonidine.

Clonidine, and more recently the highly selective α_2 adrenoceptor agonist dexmedetomidine, are used as adjuncts to general anaesthesia. They cause sedation and anxiolysis before operation, reduce haemodynamic responses, anaesthetic and analgesic requirements during operation, and reduce opioid requirements after operation [1].

The influence of α_2 agonists on respiration is uncertain. Some clinical studies have suggested that clonidine causes no or only minimal ventilatory depression [2, 3], whereas others have shown a reduction in the slope of the hypercapnic ventilatory response when clonidine was given i.v. [4] or extradurally [5]. Furthermore, episodes of arterial oxygen desaturation have occurred in association with abnormal ventilatory patterns after oral and extradural clonidine [6, 7].

α_2 Adrenergic receptors are present in the cat carotid body and they inhibit the chemoreceptor response to hypoxia [8]. Consequently, the ventilatory response to hypoxia could be attenuated by α_2 agents and thus cause more hypoxaemia in susceptible patients. However, dexmedetomidine did not affect the hypoxic ventilatory response in dogs, even at high doses [9]. Species differences may account for the discrepancy and extrapolation of animal results to humans may be inappropriate. Because of these uncertainties and as no human data are available, we have studied the effects of oral clonidine on the ventilatory response to sustained, isocapnic hypoxia in humans.

Subjects and methods

We studied 10 healthy male volunteers, none of whom was a smoker, had a history of cardiorespiratory disease or was receiving medication at the time of study. Subjects were asked to refrain from taking substances known to affect respiration (e.g. caffeine, chocolate, etc.) for a minimum of 6 h before the study and were studied after fasting for 4 h. Local Ethics Committee approval was obtained and all subjects gave written informed consent.

Each subject attended the laboratory on three occasions. The first visit was a familiarization period. A medical history was obtained and FEV_1 and FVC measurements were taken to assess and confirm normal lung function. The ventilatory response to 20 min of sustained hypoxia (Sp_{O_2} 80 %) was then measured. Each of the other 2 study days consisted of an initial control hypoxic run, followed by a further hypoxic run 1 h after either oral clonidine (approximately 3.5 μg kg^{-1} rounded up to the nearest 50 μg) or matched placebo tablets. During the 1 h wait between runs, subjects were seated in a waiting room and allowed to read. At the end of each hypoxic run, manual measurement of lying and standing arterial pressures were recorded (mercury sphygmomanometer using Korotkoff IV as end-point). To minimize the effects of diurnal variation on the hypoxic ventilatory response, studies on each subject were always scheduled for the same time of day. Neither the subject nor the assessor of ventilatory variables was aware of the treatment received.

†Presented in part at the Anaesthetic Research Society, Leeds Meeting, March 31–April 1, 1995 (*British Journal of Anaesthesia* 1995; 75: 232P–233P).

The methods used for recording ventilatory variables have been described previously [10]. Briefly, subjects were seated upright in a comfortable armchair in a well-lit room and breathed via a mouthpiece and noseclip arrangement through a low resistance two-way valve. A five-way valve (Hans-Rudolf Gatlin Valve series 2430) was connected to the inspiratory port of the two-way valve to allow changes in inspired gases without the subject's knowledge. Expiratory gas passed via a heated pneumotachograph (Fleisch No. 2) through mixing and drying chambers to a Parkinson Cowan CD4 dry gas meter modified to give a digital signal. The integrated expiratory flow signal, which gave breath-by-breath tidal volume, was calibrated against the output of the CD4 gas meter every 10 litre to correct the flow signal. Inspiratory and end-tidal oxygen ($P\mathrm{I}_{O_2}$, $P\mathrm{E}'_{O_2}$) and carbon dioxide ($P\mathrm{I}_{CO_2}$, $P\mathrm{E}'_{CO_2}$) partial pressures were measured at the lips via a mass spectrometer (VG Spectralab M). Pulse oximetry ($S\mathrm{p}_{O_2}$) (Ohmeda Biox 3700, set to a fast averaging time of 2 s) and electrocardiogram (Hewlett-Packard 78351A) were measured continuously throughout the study.

Breath-by-breath values of inspiratory time ($T\mathrm{I}$, s), expiratory time ($T\mathrm{E}$, s), total breath time ($T\mathrm{Tot} = T\mathrm{I} + T\mathrm{E}$, s), ventilatory frequency ($f = 60/T\mathrm{Tot}$, b.p.m.), tidal volume ($V\mathrm{T}$, litre, BTPS), instantaneous minute ventilation ($\dot{V}\mathrm{E}^{\mathrm{inst}} = f \times V\mathrm{T}$, litre, BTPS), mean inspiratory flow ($V\mathrm{T}:T\mathrm{I}$, litre s^{-1}), inspiratory time:total breath time ratio ($T\mathrm{I}:T\mathrm{Tot}$), $S\mathrm{p}_{O_2}$ (%), inspired and end-tidal partial pressures were digitized using a DEC PDP 11/23 computer and stored on disk for off-line analysis. Oxygen consumption ($\dot{V}O_2$, litre min^{-1}, STPD) and carbon dioxide output ($\dot{V}CO_2$, litre min^{-1}, STPD) were measured from collections of mixed expired gas made over 2-min periods and the gas exchange ratio calculated (R). During each run subjects listened to music through headphones and were asked to remain awake. Subjects were aroused by an observer if they appeared to be asleep.

Measurements were made with the subjects seated at rest. Initially, room air was breathed for 15 min and duplicate measurements of $\dot{V}O_2$ and $\dot{V}CO_2$ were made between 5 and 10 min. $S\mathrm{p}_{O_2}$ was then reduced to approximately 80 % for 20 min. To achieve a square wave response, subjects were initially given two breaths of 100 % nitrogen followed by an inspired oxygen concentration of approximately 10 %. At the end of hypoxia, subjects were given one breath of 100 % before returning to 5 min of room air. All changes in gas concentrations were made during expiration. During hypoxia, carbon dioxide was added to the inspired gas to maintain $P\mathrm{E}'_{CO_2}$ as close as possible to the baseline normoxic value. Each session lasted 40 min.

Mean values for each minute for all measured ventilatory variables were calculated for each subject. In addition, mean values during the following four measurement periods of each run were calculated: baseline normoxia (A1: 4 min immediately before the onset of hypoxia); early hypoxia (H1: minutes 3–6 inclusive of hypoxia); late hypoxia (H2: minutes 17–20 inclusive of hypoxia); and normoxic recovery (A2: minutes 2–5 inclusive after return to breathing room air). Three further variables were derived: the acute hypoxic ventilatory response (AHR) was calculated as the difference between periods A1 and H1, the absolute magnitude of the decline in ventilation during sustained hypoxia (HVD) was calculated as the difference in ventilation between periods H1 and H2, and the off-response was calculated as the difference in ventilation between periods H2 and A2.

Group means and SD for imposed respiratory variables and group means and confidence limits (CL) for studied respiratory variables in the four measurement periods, including the three derived variables, were calculated for each run. Within a run, the respiratory variables in the four measurement periods were subjected to one-way analysis of variance with *post hoc* multiple comparisons with the Scheffé test. Both placebo and clonidine runs were compared with their respective control runs using the Student's paired t test. $P < 0.05$ was taken as significant. All computations were carried out using the SPSS for Windows version 6 statistical package, run within MS DOS 6.2.

Results

All subjects completed both study days. All reported a dry mouth and drowsiness after clonidine but all remained awake during the hypoxic runs. Moderate bradycardia (40–50 beat min^{-1}) and postural hypotension were observed in the majority of subjects after clonidine but none required any intervention.

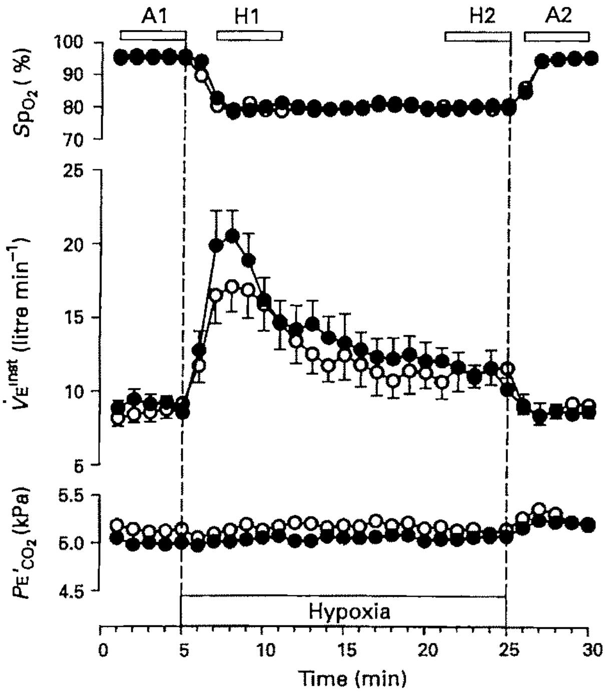

Figure 1 Oxygen saturation ($S\mathrm{p}_{O_2}$), instantaneous minute ventilation ($\dot{V}\mathrm{E}^{\mathrm{inst}}$) and $P\mathrm{E}'_{CO_2}$ plotted against time for control (○) and placebo (●) runs. Mean values for each 1-min period are presented. For clarity, SEM presented only for $\dot{V}\mathrm{E}^{\mathrm{inst}}$. Mean values for each variable were calculated over the periods A1 (baseline normoxia), H1 (early hypoxia), H2 (late hypoxia) and A2 (normoxic recovery) for each subject and used for comparison between run.

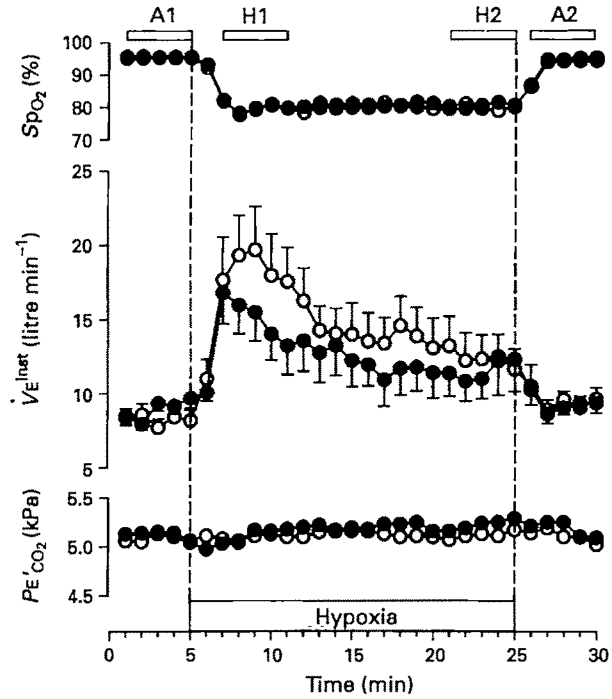

Figure 2 Oxygen saturation (Sp_{O_2}), instantaneous minute ventilation ($\dot{V}E^{inst}$) and PE'_{CO_2} plotted against time for control (○) and clonidine (●) runs. Mean values for each 1-min period are presented. For clarity, SEM presented only for $\dot{V}E^{inst}$. Periods as in figure 1.

Of the 10 subjects recruited, two appeared to develop obstructive breathing patterns after clonidine during the hypoxic phase of the run which would have made analysis of ventilatory variables difficult. We decided therefore, before analysis of the results, to eliminate the data from these two subjects, leaving eight subjects for analysis. The remaining subjects had a mean age of 34 (range 26–50) yr, mean height of 1.80 (1.64–1.92) m and mean weight of 81.7 (73.0–96.0) kg.

The pattern of ventilatory response to hypoxia was similar in all four runs (both control runs, after placebo and after clonidine) with an initial brisk increase in ventilation followed by a slower decline to a plateau (figs 1, 2). Within runs, there were no significant differences in PE'_{CO_2} for the four measurement periods or for PE'_{O_2} and Sp_{O_2} for both H1 and H2 measurement periods. Sp_{O_2} was reduced to approximately 80% during hypoxia, and PE'_{CO_2} was controlled, on average, to within 0.07 kPa of baseline normoxic values during hypoxia.

After placebo, $\dot{V}O_2$, $\dot{V}CO_2$ and respiratory quotient did not differ significantly compared with the control (table 1). Imposed variables were similar for the four measurement periods, except for very small but significant differences in Sp_{O_2} and PE'_{CO_2} during normoxic baseline and early hypoxia compared with the preceding control (table 2). After placebo, there were no significant differences in ventilatory variables, except for *f* which was significantly greater during early hypoxia, and *V*T which was significantly less during normoxic recovery. AHR did not differ between placebo and its control but HVD was significantly reduced after placebo. No significant difference between placebo and control was detected in the off-response (table 3).

After clonidine, $\dot{V}O_2$, $\dot{V}CO_2$ and respiratory quotient were not statistically different compared with the control (table 1). Imposed variables were similar for the four measurement periods, except for very small but significant differences in Sp_{O_2} during early hypoxia and PE'_{CO_2} during late hypoxia compared with the preceding control (table 4). There were no significant differences in ventilatory variables after clonidine during either normoxic baseline or recovery. After clonidine, $\dot{V}E^{inst}$, *V*T and *V*T : *T*I were significantly less during early hypoxia compared with control but there was no difference in *f*. In contrast, during late hypoxia, *f* was significantly less after clonidine but there were no significant differences in all other ventilatory variables (table 4). Both AHR and HVD were reduced significantly compared with control after clonidine. The off-response was not significantly different after clonidine (table 3).

Discussion

We have demonstrated in normal male subjects that oral clonidine, in doses used for premedication, significantly reduced the initial increase in ventilation during hypoxia but did not affect final ventilation when hypoxia was sustained for 20 min. The reduction in ventilation by clonidine during early hypoxia was caused by a reduction in *V*T with no change in *f*. This was reflected in the reduction in *V*T : *T*I which suggests an effect on respiratory drive. After placebo, ventilation was not significantly different from the preceding control run, suggesting no order effect.

We did not study females in this study because their hypoxic ventilatory response is affected by varying plasma progestogen concentrations during the menstrual cycle [11]. Consequently, studies would have had to be scheduled according to the menstrual cycle and this was impractical for volunteers. However, there is no obvious reason why the general findings do not apply to women.

Studies were conducted on 2 separate days because the long elimination half-life of clonidine [12] did

not allow within-day randomization of clonidine and placebo treatment runs. Because a subject's hypoxic ventilatory response varies from day to day [13], we did not attempt to compare placebo and clonidine treatment runs directly but added in a control hypoxic run which preceded the treatment runs. Both placebo and clonidine treatment runs were compared with their respective controls on the same day. This reduced within-subject variability of hypoxic ventilatory response and the placebo limb of the study allowed an assessment of any fixed order effect on the measured responses.

The ventilatory response to hypoxia requires 1 h to recover completely. If hypoxic tests are performed in succession, the ventilatory response to the second hypoxic test will be attenuated if inadequate time is allowed for complete recovery of the response [14]. In our studies, there was an interval of 1 h between hypoxic runs and we found no reduction in response after placebo treatment. In fact, we found that the hypoxic response after placebo was greater than the preceding control, although this was not statistically significant. It is likely therefore that the hypoxic ventilatory response had recovered completely before our second hypoxic run. Furthermore, the 1-h interval allowed oral clonidine to achieve reasonable plasma concentrations as pharmacokinetic studies have indicated that oral clonidine achieves peak concentrations at 1–2 h [12, 15].

Analysis of variance did not reveal any significant differences in $P\text{E}'_{CO_2}$ in the four measurement periods or in $S\text{p}_{O_2}$ in periods H1 and H2 within runs. However, there were significant changes between treatment and control runs in $S\text{p}_{O_2}$ and $P\text{E}'_{CO_2}$. The

differences in $S\mathrm{p}_{\mathrm{O_2}}$ between runs were very small and well within the error of the pulse oximeter used. Furthermore, $P\mathrm{E}'_{\mathrm{O_2}}$ was not significantly different between runs and as peripheral chemoreceptors respond to a reduction in oxygen tension and not to a decrease in oxygen saturation [16], these small changes in $S\mathrm{p}_{\mathrm{O_2}}$ were of no consequence. Therefore, the hypoxic stimuli were comparable between runs. With $P\mathrm{E}'_{\mathrm{CO_2}}$, the mean differences were less than 0.15 kPa between runs. After placebo, both normoxic baseline and early hypoxia $P\mathrm{E}'_{\mathrm{CO_2}}$ levels were significantly lower than control, but this was not accompanied by a lower $\dot{V}\mathrm{E}^{\mathrm{inst}}$ as expected, suggesting a large behavioural input stimulating breathing. Because $\dot{V}\mathrm{E}^{\mathrm{inst}}$ was not significantly different between placebo and control during these two measurement periods, it is likely that the larger behavioural input after placebo and the lower $P\mathrm{E}'_{\mathrm{CO_2}}$ levels did not affect the results markedly. In contrast, after clonidine, $P\mathrm{E}'_{\mathrm{CO_2}}$ level during late hypoxia was significantly greater than control and this could have overestimated ventilation during late hypoxia, although the effect is likely to have been small.

Two subjects were excluded from analysis because of apparent episodes of obstructive apnoea, mainly during the hypoxic period after clonidine treatment. Neither recalled these obstructive episodes and it is likely that sedation was responsible. Sedation and obstructive apnoeas after oral clonidine have been reported in a previous study [6]. None of the other subjects had clinical evidence of upper airway obstruction after clonidine but it is possible that subclinical obstructive apnoea did occur during the study. However, it is unlikely that our results were caused entirely by the effects of upper airway obstruction. In this study, we were unable to resolve the question of whether or not clonidine reduced the ventilatory response to hypoxia directly or via its sedative effects leading to obstructive apnoeas. It has also been suggested that the ventilatory effects of clonidine may be caused by changes in sleep state [5]. Although our subjects felt sedated after clonidine to varying degrees, none demonstrated a significant reduction in oxygen consumption or carbon dioxide production and neither ventilation nor $P\mathrm{E}'_{\mathrm{CO_2}}$ changed during normoxic baseline after clonidine. Previous work suggests that these variables would be altered if the subjects were asleep [17, 18]. Therefore, our results are unlikely to be caused by a change in sleep state induced by clonidine.

Both AHR and HVD were reduced after clonidine compared with control. This is in keeping with the observation that the magnitude of the hypoxic ventilatory decline is related to the acute hypoxic response [19]. Although the off-response was not significantly different from control, in three of eight subjects, clonidine caused ventilation at the end of hypoxia to be lower than normoxic baseline values. This suggests that in some subjects, under conditions of sustained hypoxia, clonidine may accentuate HVD. However, the number of subjects used in the current study is too small to comment further. An anomaly of this study was that although AHR was not significantly different after placebo compared with control, HVD after placebo was greater (table 3). There is no obvious reason for this. It is possible that this was the result of a placebo effect causing an alteration in behavioural state and ventilatory control.

Human studies have concentrated so far on the influence of clonidine on the hypercapnic ventilatory response. An i.v. dose of 3 $\mu g\ kg^{-1}$ attenuated the hypercapnic response significantly by reducing the slope of the carbon dioxide response line [4]. This was also the case after 300 μg given extradurally [5]. Two studies using oral clonidine (range 3.5–5 $\mu g\ kg^{-1}$) did not demonstrate a reduction in the slope of the carbon dioxide response line [2, 3]. However, Bailey and co-workers did find rightward displacement of the ventilatory response to carbon dioxide after clonidine [2] and Jarvis and co-workers found significant depression of mean inspiratory flow rate ($V_T:T_I$) [3]. Therefore, it is likely that clonidine does alter the ventilatory response to hypercapnia both by reducing the slope and by rightward shift of the response. We chose an oral dose of 3.5 $\mu g\ kg^{-1}$ for our subjects as this was comparable with the doses used in the hypercapnic studies.

Information on the effect of clonidine on the hypoxic ventilatory response in humans is lacking and animal studies have yielded conflicting results. Kou and colleagues [8] demonstrated the presence of α_2 adrenergic receptors in the carotid bodies of cats and that guanabenz, an α_2 agonist similar to clonidine, reduced the carotid sinus nerve discharge in response to hypoxia. In a later study on dogs using dexmedetomidine, a more specific α_2 adrenergic agonist, Nguyen and colleagues [9] found no significant change in the hypoxic ventilatory response. Our study has shown that the initial increase in ventilation in response to hypoxia (lasting 3–8 min) was attenuated by clonidine by an average of 3.91 litre min^{-1} (95% confidence limit 2.27, 5.55 litre min^{-1}) but did not affect the subsequent decline in ventilation when hypoxia was sustained. Animal studies have further suggested that the direct effects of catecholamines, their antagonists and volatile anaesthetic agents on peripheral chemoreceptors disappear in severe hypoxia (< 5.3 kPa) [20, 21]. The effect of clonidine on the hypoxic ventilatory response may be overcome by more severe hypoxia, but as we only examined the effect of clonidine at one level of hypoxia, we cannot predict the effect in more severe hypoxia. The exact mechanism by which clonidine reduced the hypoxic ventilatory response remains unclear. The peripheral chemoreceptors may be involved but a central effect of clonidine cannot be excluded.

This effect of clonidine could have contributed to the episodes of oxygen desaturation reported by previous investigators [6, 7]. However, these investigators suggested that obstructive apnoeas caused by sedation after clonidine were responsible for the instability in oxygenation. Apart from its sedative action, clonidine may exacerbate these obstructive apnoeas via an effect on peripheral chemoreceptors. Increased arousal from chemical stimuli to breathing increases the tone of upper airway muscles, and hypoxia is an important stimulus [22]. Clonidine may have attenuated this reflex at the peripheral chemoreceptors. Therefore, it is likely that clonidine can cause oxygen desaturations through both its sedative effect and via an effect on the peripheral chemoreflex pathway.

In conclusion, we have demonstrated that clonidine reduced the initial increase and subsequent reduction in ventilation during sustained hypoxia. However, the absolute level of ventilation at the end of the hypoxic period was unchanged. Blunting of this protective mechanism suggests that the use of clonidine in patients requires respiratory monitoring, especially when used with other agents which depress ventilation.

Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation

K. MIKAWA, K. NISHINA, N. MAEKAWA AND H. OBARA

Summary

We have compared the efficacy of three calcium channel blockers, nicardipine, diltiazem and verapamil, in attenuating the cardiovascular responses to laryngoscopy and intubation in 60 normotensive patients (ASA I) undergoing rapid sequence induction of anaesthesia with thiopentone and fentanyl. We also examined whether or not these blockers inhibited catecholamine release induced by intubation. The patients were allocated to one of four groups ($n = 15$ for each): saline (control), nicardipine 30 µg kg^{-1}, diltiazem 0.2 mg kg^{-1} or verapamil 0.1 mg kg^{-1}. Verapamil and the three other drugs were administered 45 s and 60 s before the start of direct laryngoscopy, respectively, in a double-dummy design. Anaesthesia was induced with thiopentone 4 mg kg^{-1} i.v. and fentanyl 2 µg kg^{-1} i.v. Tracheal intubation was facilitated with vecuronium 0.2 mg kg^{-1}. During anaesthesia, ventilation was assisted or controlled with 1% isoflurane and 50% nitrous oxide in oxygen. Laryngoscopy lasting 30 s was attempted 2 min after administration of thiopentone and vecuronium. Patients receiving saline exhibited significant increases in systolic and diastolic arterial pressures (AP), heart rate (HR) and plasma concentrations of catecholamines associated with tracheal intubation. The increase in AP was attenuated in patients treated with any calcium channel blocker. The greatest effect was elicited by verapamil, which attenuated the increase in HR, although nicardipine seemed to enhance tachycardia. All three drugs failed to suppress the increase in plasma catecholamine concentrations in response to tracheal intubation. These findings suggest that bolus injection of verapamil 0.1 mg kg^{-1} was a more effective method of controlling hypertension and tachycardia associated with intubation than diltiazem 0.2 mg kg^{-1} or nicardipine 30 µg kg^{-1}, and that these prophylactic effects were not caused by inhibition of the catecholamine response. (*Br. J. Anaesth.* 1996; **76**: 221–226)

Key words

Intubation tracheal responses. Calcium channel block, diltiazem. Calcium channel block, nicardipine. Calcium channel block, verapamil. Complications, hypertension. Cardiovascular system, effects.

Laryngoscopy and tracheal intubation after a standardized induction dose of thiopentone often provoke a reflex increase in both sympathetic and sympathoadrenal activity, which may result in hypertension, tachycardia and arrhythmias [1–7]. These responses, although transient, may be harmful in some patients, particularly those suffering from myocardial or cerebrovascular disease. Many pharmacological techniques have been devised to reduce the extent of the haemodynamic events, including the use of high-dose opioids [1], local anaesthetics [1], adrenergic blocking agents [1] and vasodilating agents such as nitroglycerin [2] and sodium nitroprusside [3]. Several studies have shown that calcium channel blockers such as nicardipine [4], diltiazem [5] or verapamil [6, 7] are also effective. However, the effects of these calcium channel blockers have been examined separately with different anaesthetic induction techniques, including different anaesthetics and neuromuscular blockers. Thus the aim of the present study was to compare the efficacy of single rapid administration of verapamil, diltiazem and nicardipine for controlling these haemodynamic responses to tracheal intubation under the same anaesthetic techniques.

A good correlation has been demonstrated between the cardiovascular responses to intubation and changes in plasma catecholamine concentrations [8–11]. Calcium ions exert a major role in the release of catecholamines from the adrenal gland and adrenergic nerve endings, which affects plasma concentrations of catecholamines, in response to sympathetic stimulation [12]. Animal experiments have shown that calcium channel blockers inhibited catecholamine release from the sympathetic nerve ending by electrical stimulation [13–15]. In a study in healthy volunteers, the blocker inhibited the increase in plasma adrenaline induced by exercise [16]. These observations suggest that calcium channel blockers interfere with catecholamine release after tracheal intubation. In addition, therefore, plasma concentrations of catecholamines were measured before and after intubation with or without prior administration of the calcium channel blockers.

Patients and methods

The study was approved by the Ethics Committee of Kobe University Hospital. We studied 60 normo-

tensive patients (ASA I) undergoing elective surgery; all gave informed consent. They were allocated randomly to one of four groups ($n = 15$ for each group) to receive saline (control), nicardipine 30 μg kg^{-1} (Perdipine, Yamanouchi, Japan), diltiazem 0.2 mg kg^{-1} (Herbesser, Tanabe, Japan) or verapamil 0.1 mg kg^{-1} (Vasolan, Eisai, Japan). Patients with anticipated difficult tracheal intubation, hypertension, renal, hepatic or gastrointestinal disease, or weight exceeding 120% of ideal for height were excluded (Table 1).

Premedication consisted of oral diazepam 0.1 mg kg^{-1} and atropine 0.01 mg kg^{-1} i.m., given at 60 min and 30 min, respectively, before induction of anaesthesia, which started at 08:30 in all subjects. On arrival in the operating room, two (right and left) radial arterial cannulae were inserted under local anaesthesia for continuous monitoring of systolic (SAP) and diastolic (DAP) arterial pressure using a Cardiocap (Datex, Helsinki, Finland) and for blood sampling for measurement of plasma concentrations of catecholamines. Heart rate (HR) was monitored by electrocardiography (ECG lead II). After a 10-min stabilization period, the patients breathed 100% oxygen via a mask for 3 min. Immediately before induction of anaesthesia (time = 0), arterial blood was obtained for catecholamine analysis, and SAP, DAP and HR were recorded simultaneously by independent observers to obtain the operating room baseline. Anaesthesia was then induced in a rapid sequence fashion with thiopentone 4 mg kg^{-1} and fentanyl 2 μg kg^{-1} followed by vecuronium 0.2 mg kg^{-1} to facilitate tracheal intubation. Direct laryngoscopy was attempted 2 min after thiopentone–vecuronium and maintained for 30 s. The tracheal tube was inserted within the last 5 s of laryngoscopy with the aid of a standard Macintosh laryngoscope blade. All intubations were performed by the same anaesthetist (K.M.). A double–dummy technique was used to maintain a double-blind design (table 2). All patients received two injections. In the verapamil group, saline and verapamil were administered i.v. 60 s and 45 s before the start of direct laryngoscopy, respectively. In the diltiazem and nicardipine groups, the calcium channel blocker and saline were injected 60 s and 45 s before starting laryngoscopy. These doses and timings were based on our previous data [4–6]. In these reports, the three calcium channel blockers were shown to attenuate the pressor response to tracheal intubation to a similar extent (16–18% attenuation of mean arterial pressure). Furthermore, the doses of the calcium channel blockers used in the present study produced a similar degree of hypotension in patients anaesthetized with enflurane and nitrous oxide, without noxious surgical stimulation [4–6]: nicardipine 30 μg kg^{-1}, verapamil 0.1 mg kg^{-1} and diltiazem 0.2 mg kg^{-1} decreased mean arterial pressure by 30%, 27% and 24%, respectively. Other investigators administered nicardipine and diltiazem for the treatment of hypertension during surgery [17, 18]. Nicardipine 25–30 μg kg^{-1} produced a 25% reduction in SAP [17] while diltiazem 10 mg (0.2 mg kg^{-1} by estimation) i.v. decreased SAP by 21% [18]. Verapamil 0.1 mg kg^{-1} or 5 mg i.v. caused a 25% decrease in SAP in patients with renal hypertension [19]. These findings determined our selection of the doses of the three calcium channel blockers.

After administration of thiopentone and vecuronium until 10 min after induction, ventilation was assisted as required or controlled with 1% isoflurane and 50% nitrous oxide in oxygen, and end-tidal partial pressure of carbon dioxide was maintained at 4.1–5.1 kPa, monitored with a Datex Capnometer (Helsinki, Finland) by means of a catheter placed in the nostril. After insertion of the tracheal tube, sampling of expired air was performed from a T-piece connected to the tube. Additional blood samples and haemodynamic measurements were obtained immediately before induction, and 1, 2, 2.5, 2.75, 3, 4 and 5 min after administration of thiopentone–vecuronium by independent observers who were blinded to the nature of the experimental treatment. All measurements and blood sampling were completed before surgical skin incision. SAP, DAP, HR and plasma concentrations of catecholamines were compared with corresponding measurements in the four groups and with measurements

Table 2 Timing of administration of calcium channel blockers and saline in the four groups (double-dummy technique). All doses of drug were prepared in 10 ml

	First drug	Second drug
Group	60 s after thiopentone–vecuronium (60 s before laryngoscopy)	75 s after thiopentone–vecuronium (45 s before laryngoscopy)
Control	Saline	Saline
Nicardipine	Nicardipine 30 μg kg^{-1}	Saline
Diltiazem	Diltiazem 0.2 mg kg^{-1}	Saline
Verapamil	Saline	Verapamil 0.1 mg kg^{-1}

before induction (operating room baseline) within the same group. Maximal values of SAP, DAP and HR after intubation were also recorded.

CATECHOLAMINE MEASUREMENT

Arterial blood for measurement of plasma concentrations of catecholamine, was collected in lithium heparin tubes and centrifuged within 10 min at 0 °C. Plasma was separated and stored at −70 °C until assay by reverse phase high-pressure liquid chromatography with electrochemical detection and an internal standard using the method described by Krstulovic [20] and Causon and Carruthers [21]. The lower limits of sensitivity of the method were 54.6 pmol litre^{-1} and 0.0591 nmol litre^{-1} for adrenaline and noradrenaline, respectively. The intra- and inter-assay coefficients of variance were, respectively, 4.4 % and 8.0 % for adrenaline and 4.8 % and 8.4 % for noradrenaline.

STATISTICS

Statistical analysis was performed using analysis of variance followed by Bonferroni's modification of *t* test for parametric data, and Fisher's exact test for non-parametric (distribution) data. Differences were considered statistically significant at $P < 0.05$. The power of the present study was 75 % provided that d $(= \mu - \mu'/\sigma)$ is 1.0 (where μ, μ' = mean and σ = SD). Thus the number of patients in the present study ($n = 15$) was sufficient to detect such a difference between groups.

Results

The four groups were comparable in age, weight and sex (table 1).

There were no significant differences between the four groups in SAP immediately before the start of laryngoscopy or before induction. In response to laryngoscopy and intubation, SAP and DAP increased significantly in the control group, while the increases were significantly less in the groups treated with calcium channel blockers (figs 1, 2). Administration of verapamil 0.1 mg kg^{-1} completely inhibited the increase in arterial pressures associated with intubation. Diltiazem 0.2 mg kg^{-1} seemed to be less effective than the two other calcium channel blockers. Conversely, in the verapamil group, arterial pressures decreased 5 min after induction compared with before induction, although the two other blockers did not cause such hypotension.

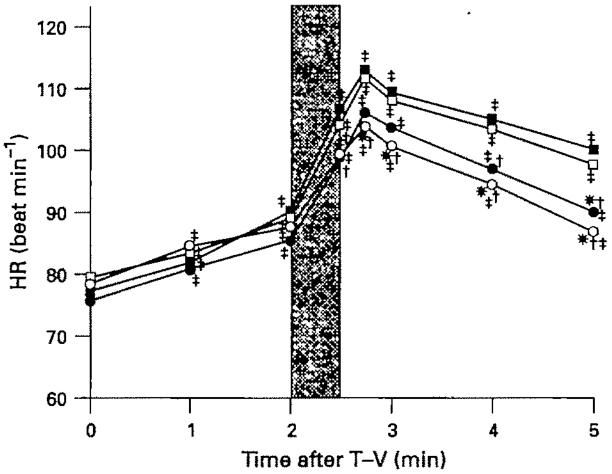

Figure 3 Mean changes in heart rate (HR) after thiopentone–vecuronium (T–V) and in response to laryngoscopy and tracheal intubation with prior calcium channel blockers (nicardipine 30 μg kg^{-1} (■), diltiazem 0.2 mg kg^{-1} (●) and verapamil 0.1 mg kg^{-1} (○)) or saline (□) (control). SEM bars are omitted for clarity. The shaded area = duration of laryngoscopy and tracheal intubation. $^{*}P < 0.05$ *vs* control; $\dagger P < 0.05$ *vs* nicardipine; $\ddagger P < 0.05$ *vs* pre-induction values within groups.

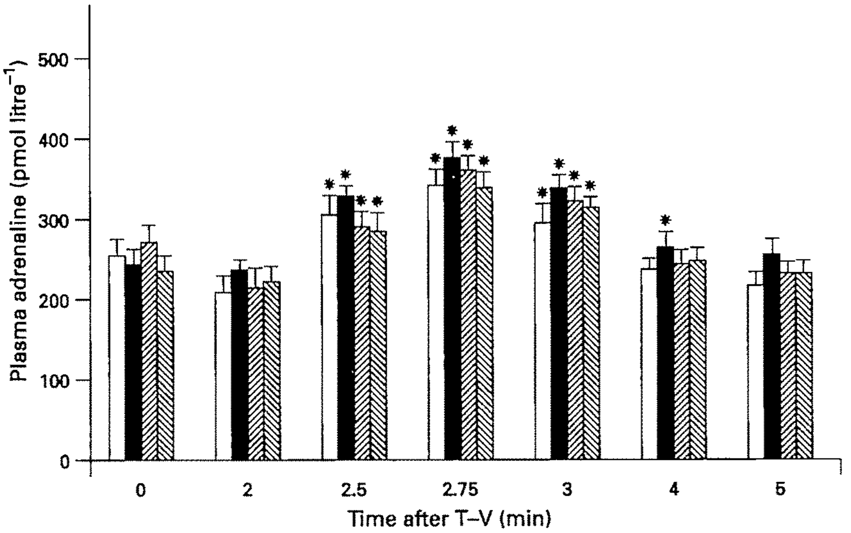

Figure 4 Changes in plasma adrenaline concentrations (mean, SEM) after thiopentone–vecuronium (T–V) and in response to laryngoscopy and tracheal intubation with prior calcium channel blockers (nicardipine 30 µg kg^{-1} (■), diltiazem 0.2 mg kg^{-1} (▨) and verapamil 0.1 mg kg^{-1} (▧)) or saline (□) (control). Data at 1 min after induction are omitted. *$P < 0.05$ *vs* pre-induction values within groups.

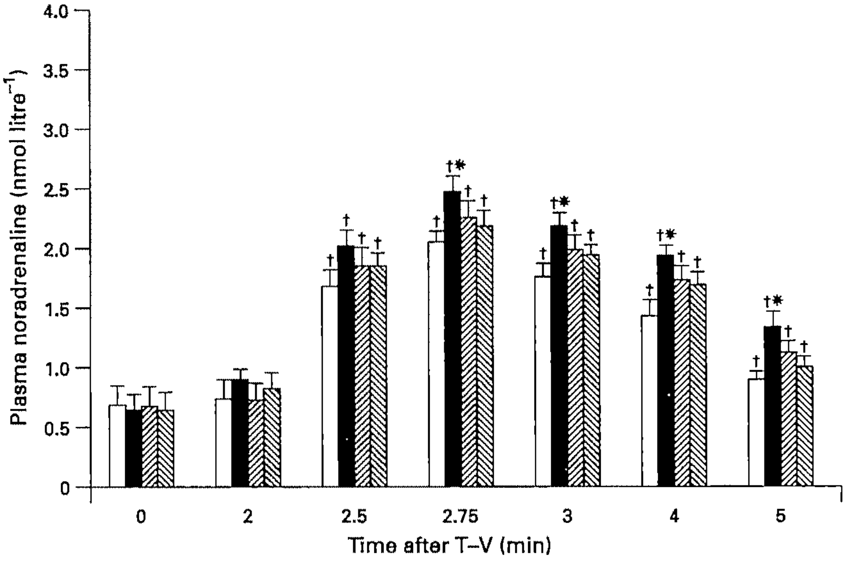

Figure 5 Changes in plasma noradrenaline concentrations (mean, SEM) after thiopentone–vecuronium (T–V) and in response to laryngoscopy and tracheal intubation with prior calcium channel blockers (nicardipine 30 µg kg^{-1} (■), diltiazem 0.2 mg kg^{-1} (▨) and verapamil 0.1 mg kg^{-1} (▧)) or saline (□) (control). Data at 1 min after induction are omitted. *$P < 0.05$ *vs* control; †$P < 0.05$ *vs* pre-induction values within groups.

Although there was an increase in HR after induction, there was no significant difference in pre-induction values of HR or that immediately before laryngoscopy between the four groups. Verapamil successfully attenuated the HR increase after intubation (fig. 3). In contrast, nicardipine failed to do so. HR was lower in the verapamil and diltiazem groups than in the nicardipine group.

There were no significant differences in plasma adrenaline and noradrenaline concentrations between the four groups at the pre-induction and pre-intubation times. Plasma adrenaline concentrations increased significantly after intubation, with return towards baseline by 5 min after induction in all groups (fig. 4). The calcium channel blockers failed to attenuate the increase. Plasma noradrenaline concentrations increased in response to intubation in the control group. The increase was enhanced in patients receiving nicardipine (fig. 5). Verapamil and diltiazem showed changes similar to those in the control group.

A significantly smaller number of patients receiving calcium channel blockers demonstrated an SAP > 170 mm Hg and a DAP > 110 mm Hg (table 3). The number of patients with HR > 100 beat min^{-1} seemed to be smaller in the verapamil than in the control group, although this was not significant. HR > 100 beat min^{-1} was observed less frequently in patients receiving verapamil than in those receiving nicardipine.

No abnormal changes in ECG were observed in any patient in the diltiazem and verapamil groups. In contrast, one patient in the control and nicardipine groups had short-lived ventricular premature con-

Table 3 Number of patients demonstrating systolic (SAP) or diastolic (DAP) hypertension and tachycardia by treatment groups ($n = 15$ for each group). Significant difference ($P < 0.05$) compared with: * control group, † nicardipine group

tractions. During this study, no patient developed hypotension ($SAP < 80$ mm Hg) or bradycardia ($HR < 50$ beat min^{-1}) severe enough to require pressor, anticholinergic or sympathomimetic agents: the lowest SAP/DAP values were 82/49, 82/50 and 85/52 mm Hg in the verapamil, nicardipine and diltiazem groups, respectively, and the lowest HR were 57, 79 and 63 beat min^{-1} in the verapamil, nicardipine and diltiazem groups, respectively.

Discussion

Consistent with previous reports [4–7], we have confirmed that these calcium channel blockers attenuated hypertension associated with tracheal intubation. Verapamil successfully blunted tachycardia, unlike nicardipine and diltiazem. These findings may be explained by the difference in pharmacological characteristics between dihydropyridines and phenylalkylamines. In our previous study [6], verapamil failed to attenuate the increase in HR. This discrepancy may result from different anaesthetic induction techniques: we administered fentanyl as a supplement in the present study. The concomitant use of fentanyl has been shown to potentiate the slowing effect of verapamil on HR [22]. Although we reported previously that diltiazem 0.3 mg kg^{-1} was more effective against the pressor response than 0.2 mg, our preliminary study revealed that the dose of 0.3 mg in the present study caused severe hypotension ($SAP < 75$ mm Hg) in two of five patients. This may result from interaction between diltiazem and fentanyl. Thus these observations did not justify the use of this dose.

In patients with coronary artery disease (CAD) or those with risk factors for CAD, myocardial ischaemia may occur during the induction–intubation sequence [23]. Intraoperative ischaemia has been associated with a high rate of perioperative myocardial infarction. Because HR is a major determinant of myocardial oxygen balance [24], the effect of verapamil on tachycardia may justify the use of the drug, whereas the lack of efficacy of nicardipine may limit its usefulness.

We have also confirmed previous findings [8–11] that laryngoscopy and tracheal intubation after a combination of thiopentone and a neuromuscular blocking agent cause significant increases in plasma concentrations of catecholamines. No calcium channel blocker attenuated the catecholamine response to intubation, and conversely nicardipine enhanced the increase. Some investigators have documented that short-term treatment using dihydropyridine-type drugs increases plasma concentrations of noradrenaline as a result of baroceptor-mediated reflex in sympathetic nervous activity [25, 26]. Furthermore, verapamil and diltiazem had no effect on plasma concentrations of noradrenaline [27, 28]. These reports support our observations. In the present study, despite higher plasma concentrations of noradrenaline in patients receiving nicardipine than in the control after intubation, the increase in arterial pressure was lower in the nicardipine group during the study period. Philipp, Distler and Cordes documented that an important determinant of the level of arterial pressure may be plasma noradrenaline and reactivity to noradrenaline [29]. Calcium channel blockers have been shown to reduce the pressor effect of circulating noradrenaline on resistance vessels [30], resulting from inhibition of the calcium influx that accompanies stimulation of α_2 receptors [31], leading to attenuation of the increase in arterial pressure after elevated concentrations of noradrenaline.

No patient in the present study developed severe hypotension: the lowest SAP and DAP recorded were 82 mm Hg and 49 mm Hg, respectively, in a patient receiving verapamil 5 min after induction. There were no differences between the three groups in clinical outcome (e.g. intra- and postoperative mortality and morbidity), possibly because we studied only otherwise healthy ASA I patients without cardiovascular or cerebrovascular disease.

Preoperative infusion of amino acids prevents postoperative hypothermia

E. SELLDÉN, R. BRÄNSTRÖM AND T. BRUNDIN

Summary

Intraoperative infusion of amino acids has been found to stimulate energy expenditure and thereby prevent anaesthesia-induced hypothermia. Rectal temperature and respiratory gas exchange were measured in 24 female patients before and after isoflurane anaesthesia. Sixteen patients had an amino acid mixture of 240 kJ h^{-1}, infused over 1–2 h before anaesthesia and eight control patients received saline. We compared the results with data from six female volunteers treated with amino acids; they were not premedicated or anaesthetized. In lorazepam premedicated patients, amino acids increased the pre-anaesthesia temperature by 0.3 °C h^{-1}, twice that observed in the volunteers. At awakening after anaesthesia, energy expenditure increased to 50–60% above baseline in the amino acid treated patients, while in the control patients, receiving saline, no increase occurred, despite vigorous shivering. Amino acid infusion prevented hypothermia by increasing heat accumulation and causing delayed stimulation of heat production. The heat accumulation response to amino acid infusion was increased after premedication with lorazepam. (*Br. J. Anaesth.* 1996; **76**: 227–234)

Key words
Hypothermia. Protein, amino acids. Temperature, body. Temperature, metabolism.

Anaesthesia-induced hypothermia constitutes a clinical problem by causing impaired blood coagulation [1], prolonged drug action [2], negative postoperative nitrogen balance [3] and reduced resistance to surgical wound infections [4]. Consequently, several devices to combat hypothermia have been developed [5, 6]. Most of these are designed to minimize heat loss from the body surface. However, general anaesthesia does not induce hypothermia solely by interfering with regulation of heat dissipation. Most anaesthetics also reduce considerably heat generation by suppressing whole body oxidative metabolism [7–9]. Little attention has been paid to preventing the development of anaesthesia-induced hypothermia by stimulating the generation of heat.

It is well known from earlier studies that in the unanaesthetized state, administration of nutrients, especially protein and amino acid mixtures, stimulates resting energy expenditure (see [10]). Moreover, approximately 60 % of the extra heat produced in response to amino acid administration accumulates, thus increasing the temperature of mixed venous blood [11–14]. We recently found that the mechanisms for nutrient-induced thermogenesis are not impaired during general anaesthesia [15]. In contrast, the thermic effect of amino acids was found to be increased five-fold during, and most markedly, immediately after isoflurane–nitrous oxide anaesthesia. The enhanced amino acid-induced thermogenesis counteracted the anaesthesia-induced reduction in metabolism and prevented the development of hypothermia. However, amino acid infusions started at the onset of anaesthesia did not prevent the initial reduction in temperature that occurred within the first 20 min of anaesthesia [15].

The present study was designed to see if starting or completing the amino acid infusion before the onset of anaesthesia would induce heat production, which would be more effective in reducing the initial decrease in temperature and thereby counteract the development of anaesthesia-induced hypothermia more effectively than intraoperative infusions. Therefore, patients admitted for elective surgery were given amino acid infusions over 1–2 h before induction of anaesthesia. Body temperature was measured before, during and after anaesthesia. Energy expenditure was measured before amino acid infusions, immediately before and soon after anaesthesia. The results were compared with those from a control patient group receiving nutrient-free saline solutions, and a group of healthy individuals not subjected to premedication or anaesthesia.

Patients and methods

We studied 24 female patients and six healthy women. The patients were undergoing hysterectomy because of menorrhagia and were otherwise healthy, receiving no medications (table 1). Eight of the patients (group A) had amino acids infused i.v. for 1 h before anaesthesia and continuing throughout the first hour of anaesthesia. Eight patients (group B) had amino acids infused for 2 h before the onset of anaesthesia. Eight control patients (group C) had corresponding volumes of nutrient-free saline solution infused for 1 h before and the first hour of

anaesthesia. The six healthy female volunteers (group D) not subjected to premedication or anaesthesia, reported to the laboratory after an overnight fast. They were studied before and over the 4 h after the onset of a 2-h amino acid infusion, identical to that given to the patients (groups A and B). All subjects were informed of the nature, purpose and possible risks of the study before giving consent to participate. The study was reviewed and approved by the institutional Ethics Committee.

The first 16 patients studied were allocated to groups A and C. Otherwise the patients were not randomized. The study was not blinded. Patients in group B, receiving the entire 2-h infusion of amino acids before the onset of anaesthesia were studied later, as was the volunteer group. All patients were prepared according to standard preoperative routines. All studies, including those in the volunteers, were started at 07:30 after an overnight fast of 12–14 h. At 3 h before anaesthesia the patients received oral premedication with lorazepam 1–2 mg. In the patients and volunteers, a thermometer probe was inserted in the rectum 10–15 cm and two arm veins were cannulated. One catheter for amino acid infusion was inserted and advanced centrally, 30 cm, to reach the subclavian vein. A cubital vein of the other arm was cannulated for blood sampling. Except for 1 u. of warmed blood, given to one of the controls during anaesthesia, no warming device was used. The nutrient-free saline infusions (500 ml h^{-1}) were given at room temperature to all patients during operation.

Respiratory gas exchange was measured for 6–10-min periods by continuous breath-by-breath analysis (Medigraphics, System CPX/D, Medical Graphics Corp., St Paul, MN 55127, USA) using a noseclip and mouthpiece technique with which the subjects had been previously familiarized. The apparatus used for gas exchange analysis, periodically controlled in the laboratory for gas flow and gas concentrations, was calibrated for gas flow and concentrations using a 3 litre precision syringe and calibrated gases before each study. During periods of gas collection, the gas flow and concentrations were measured continuously and gas exchange automatically calculated and recorded each 20 s. Frequent recording facilitates immediate detection of a gas leakage, which may occur, especially when collecting expired gas in the early postoperative period.

Before the amino acid or saline infusions were started, baseline measurements were made of temperature, heart rate, arterial pressure and pulmonary gas exchange. Rectal temperature was measured each 1 min, either digitally, as described earlier [16], or with an Exagon thermometer (MC 8700, Roskilde, Denmark) throughout the observation period, that is before, during and after anaesthesia until 4 h after the end of the amino acid infusion for the patients; and before, during and 2 h after the amino acid infusion for the volunteers. After each study, the probes were calibrated with the same precision thermometer. Room temperature was monitored continuously and maintained at 21–23 °C. Blood samples for analysis of free plasma amino acids were obtained twice, at the end of the amino acid–saline infusion and 2 h later.

During recovery from anaesthesia, patients were observed by the same observer for the presence or absence of obvious generalized shivering. Postoperative pain relief was given to all patients after measurement of gas exchange after operation. In Group A, after baseline measurements at 1 h after premedication, a mixture of 19 amino acids (Vamin 18 g N/litre, Pharmacia, Sweden) was infused i.v. at a rate of 126 ml h^{-1}, corresponding to 240 kJ of energy per hour over 2 h. After 60 min of infusion, measurements of pulmonary gas exchange were repeated ("before anaesthesia"), and immediately after that, the patients were anaesthetized. The amino acid infusion then continued during the first hour of anaesthesia. Within 5 min after emergence from anaesthesia, analysis of pulmonary gas exchange was repeated ("after anaesthesia"). Mean duration of anaesthesia in group A was 144 (SEM 9) min and that of surgery 90 (7) min. In group B, patients received an amino acid infusion, identical to that given in group A. However, it was given 2 h before anaesthesia. When the amino acid infusion ceased, measurements of pulmonary gas exchange were repeated ("before anaesthesia"), after which anaesthesia was induced. Within 5 min after the end of anaesthesia, analysis of pulmonary gas exchange was repeated ("after anaesthesia"). In group B, mean duration of anaesthesia was 128 (13) min and that of surgery 88 (12) min. In group C, control patients were treated in the same manner as group A, but they received equal volumes of nutrient-free Ringer's solution instead of amino acids for 1 h before anaesthesia and during the first hour of anaesthesia. Pulmonary gas exchange measurements were performed and repeated as in group A. In group C the duration of anaesthesia was 154 (11) min and that of surgery 99 (7) min. Differences in duration of anaesthesia and surgery represent the time necessary for the routine procedures of anaesthesia and pre-surgical preparation of the patients. In group D, healthy volunteers were studied in the morning after an overnight fast and 30 min rest in the laboratory. After baseline measurements they received a 2-h amino acid infusion identical to that given to patients in groups A and B. Measurements were then repeated every 30 min until 2 h after the end of the amino acid infusion.

The dose of the amino acid mixture, 240 kJ h^{-1}, was identical to that given during operation in our earlier study of anaesthetized patients [15].

Anaesthesia was the same in all patients and comprised induction with thiopentone 5 mg kg^{-1} and maintenance with 1–2 % enflurane and 60 % nitrous oxide in oxygen using an Engström ventilator 2000 (Gambro Engström AB, Bromma, Sweden). All patients were monitored with pulse oximetry and capnography (Datex, Sweden). Neuromuscular block, monitored by a train-of-four technique [17], was produced with a bolus dose of atracurium 0.5 mg kg^{-1} followed by a continuous infusion of 0.5 mg kg^{-1} h^{-1}. Fentanyl 3 μg kg^{-1} was given before surgery. Atracurium infusion was terminated 0.5 h before the expected end of operation, and residual neuromuscular block was antagonized with neostigmine 2.5 mg together with atropine 0.5 mg immediately after the end of surgery. Heart rate was recorded from the electrocardiogram and arterial pressure determined by sphygmomanometry at 5-min intervals.

Energy expenditure was calculated from pulmonary gas exchange [18, 19]. Free plasma amino acids were separated by high-pressure liquid chromatography and analysed fluorimetrically using a fluorescence HPLC monitor (RF-535, Shimadzu, Tokyo, Japan). Standard statistical methods were used. For comparison between groups, data were first analysed by repeated measures ANOVA and differences then calculated by *post hoc* testing [20]. Within-group differences between baseline and later measurements were calculated using the *t* test for paired observations. Data in the text, tables and figures are given as mean (SEM).

Results

RECTAL TEMPERATURE

Baseline rectal temperatures were 36.88 (0.07) °C in patient groups A–C and 36.65 (0.10) °C in the volunteer group D (ns) (tables 2, 3). During the first hour of amino acid infusion, rectal temperature increased significantly from the basal state, by 0.20 (0.04) °C ($P < 0.001$) in the volunteers and by 0.23 (0.07) °C and 0.38 (0.09) °C in patient groups A and B, respectively (tables 2, 3, figs 1, 2). In control patients (group C), it did not change during the 1-h pre-anaesthesia infusion of saline. After 2 h of amino acid infusion, the temperature increase was 0.35 (0.04) °C in volunteers and 0.60 (0.09) °C in group B ($P < 0.05$) (tables 2, 3, fig. 3). Onset of anaesthesia caused immediate temperature reductions in all patients. During the first 30 min of anaesthesia, it decreased by 0.34 (0.04) °C in group A, 0.48 (0.10) °C in group B and 0.44 (0.07) °C in control patients (group C) (fig. 1). In group B, receiving the entire amino acid infusion before anaesthesia the initial decrease in rectal temperature closely followed that of the controls, with a steep reduction of 0.94 (0.16) °C during the first hour of anaesthesia (fig. 1).

Table 2. Rectal temperature, pulmonary oxygen uptake, respiratory exchange ratio, whole body energy expenditure and heart rate of the six healthy female volunteers (group D) studied before, during and after a 2-h period of i.v. infusion of amino acids, 240 kJ h^{-1} (mean (SEM)). *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ compared with baseline

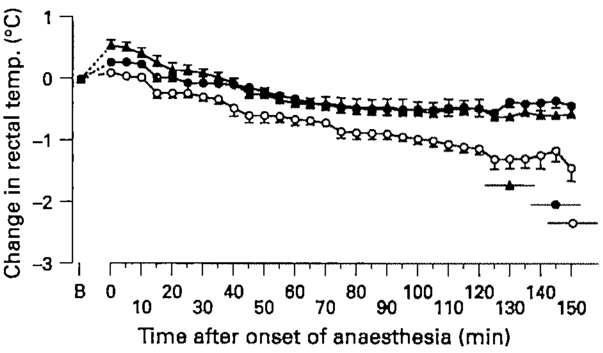

Figure 1 Changes in rectal temperature from baseline measurements (B) throughout anaesthesia in eight patients receiving amino acid infusion for 1 h before and 1 h of anaesthesia (●), eight patients receiving amino acids for 2 h before anaesthesia (▲) and eight patients receiving a nutrient-free saline solution for 1 h before and 1 h of anaesthesia (○). Vertical bars = SEM of mean changes, horizontal bars = SEM of awakening time.

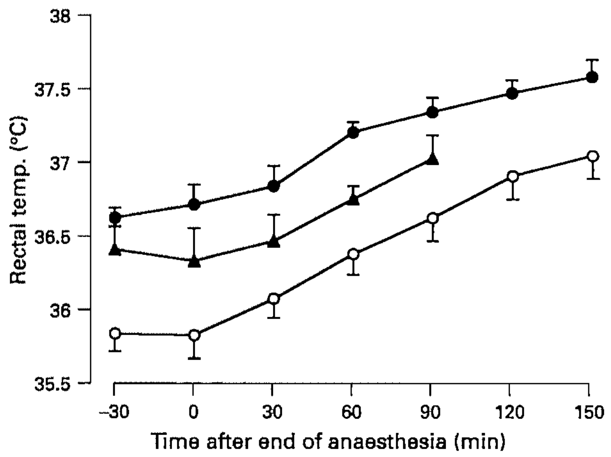

Figure 2 Rectal temperature in absolute terms measured after the end of anaesthesia. Patient groups and symbols as in figure 1.

However, the decrease in temperature from the onset of anaesthesia was significantly greater in the control group than in both the amino acid treated groups throughout anaesthesia. At awakening after 144 (9) and 128 (13) min of anaesthesia in groups A and B, respectively, the temperature decline had not reduced the temperatures to levels significantly below baseline values. When the control patients awakened after 154 (11) min of anaesthesia, mean temperature was 1.00 (0.08) °C below the baseline level ($P < 0.01$) (table 3, fig. 2). This group required approximately 100 min in postoperative recovery to return to baseline temperature levels (fig. 2). In the volunteers, not subjected to premedication or anaesthesia, rectal temperature increased by 0.35 (0.04) °C during infusion and continued to increase for 90 min after the amino acid infusion ceased and remained at its maximum when the study ended (table 2, fig. 3).

PULMONARY OXYGEN UPTAKE

Baseline oxygen consumption did not differ significantly between the patient groups (table 3). Baseline values for oxygen consumption in the volunteers (196 (8) ml min^{-1}) did not differ from those in the

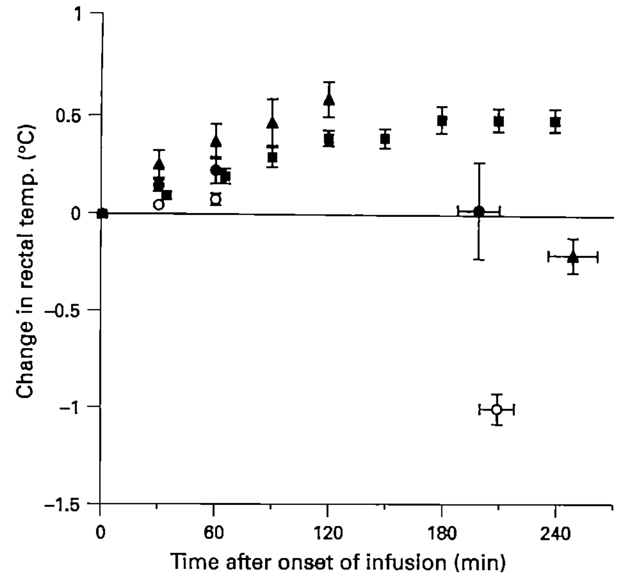

Figure 3 Changes in rectal temperature from onset of i.v. amino acid–saline infusion in eight patients receiving an amino acid infusion for 1 h before and 1 h of anaesthesia (●), eight patients receiving amino acids for 2 h before anaesthesia (▲), eight patients receiving a nutrient-free saline solution for 1 h before and 1 h of anaesthesia (○) and six unanaesthetized volunteers, receiving identical amino acid infusions for 2 h (■). Vertical bars = SEM of mean changes, horizontal bars = SEM of awakening time.

amino acid treated groups (A and B). After 1 h of preoperative amino acid infusion, pulmonary oxygen uptake had increased by 34 (12) ml min^{-1} in group A, and by 38 (3) ml min^{-1} in the volunteers (group D) (ns). After 2 h of preoperative amino acid infusion, oxygen uptake had increased by 34 (6) ml min^{-1} in group B, which was not different from that in group D (39 (5) ml min^{-1}) (tables 2, 3). In the controls (group C), oxygen uptake did not change from its baseline level during the 1-h pre-anaesthesia saline infusion (table 3).

At awakening, oxygen uptake increased to 85 (15) ml min^{-1} ($P < 0.001$) and 102 (45) ml min^{-1} ($P < 0.05$) above baseline in groups A and B, respectively. In group C, oxygen uptake did not significantly exceed baseline at awakening (table 3).

In the volunteer group D, maximum oxygen consumption was observed when the amino acid infusion ceased, and after that it decreased continuously. At 2 h after the end of infusion, it was still 21 (4) ml min^{-1} higher than in the basal state ($P < 0.01$) (table 2).

RESPIRATORY EXCHANGE RATIO

Baseline respiratory exchange ratio did not differ significantly between groups (tables 2, 3). In groups A and B the amino acids caused small but significant increases of 0.03 (0.01) ($P < 0.05$) and 0.04 (0.01) ($P < 0.05$), respectively. In the controls, no changes occurred. At awakening, there were no significant differences between patient groups (table 3). In volunteers, the respiratory exchange ratio did not change significantly during the amino acid infusion. However, it decreased gradually after the amino acid infusion ceased and at the end of the study was significantly lower than in the basal state (table 2).

ENERGY EXPENDITURE

Energy expenditures measured at 1 h after premedication were significantly below basal values, calculated from body dimensions and age [21] in all the patients (table 1). The differences were −9.5 (2) % ($P < 0.01$) in group A, −11.5 (4) % ($P < 0.05$) in group B and −15 (3) % ($P < 0.01$) in group C. In the untreated volunteers (group D), basal energy expenditure did not differ significantly from calculated basal values (table 2). As the changes in respiratory exchange ratio were relatively small, the changes in total energy expenditure closely followed those of pulmonary oxygen uptake. In group A it increased by 13 (4) W during 1 h of amino acid infusion, and in group B the increase after 2 h of infusion was 12 (2) W. In the control patients, energy expenditure remained essentially unchanged throughout the observation period (table 3). In the volunteers it increased during the 2-h amino acid infusion by 14 (1) W and remained significantly higher than the baseline measurements at 2 h after infusion (table 2). At awakening from anaesthesia, energy expenditure increased significantly to 88 (6) and 94 (15) W, 49 (10) and 59 (25) % above baseline levels in groups A and B, respectively.

PULMONARY VENTILATION

Baseline pulmonary ventilation was 5.4 (0.3) litre min^{-1} and 5.7 (0.4) litre min^{-1} in the amino acid treated groups A and B, respectively, and did not differ significantly from that in the control group C (5.5 (0.6) litre min^{-1}) (table 3). During the 1-h amino acid infusion before anaesthesia, it increased by 0.8 (0.2) litre min^{-1} in group A ($P < 0.05$). In group B, 2 h of pre-anaesthesia amino acid infusion increased ventilation by 0.7 (0.2) litre min^{-1} ($P < 0.05$). In the control patients, pulmonary ventilation did not change from baseline. At awakening, ventilation increased significantly by approximately 37 % and 49 % in groups A and B, respectively. In the control patients, ventilation was unchanged at awakening (table 3).

HEART RATE AND ARTERIAL OXYGEN SATURATION

At emergence from anaesthesia, heart rate significantly exceeded baseline levels in groups A and C. In the volunteers, heart rate was slightly but significantly higher than basal levels during and after amino acid infusion. Arterial oxygen saturation was unchanged during the study in all patients, being consistently 97–99 %.

SHIVERING

Shivering occurred at awakening after anaesthesia in all control patients, but in none of the patients in group A. In group B, two patients shivered after anaesthesia.

PLASMA CONCENTRATION OF FREE AMINO ACIDS

The control patients (group C) had normal plasma concentrations for the 21 amino acids analysed [22] after 1 h of anaesthesia, and also 2 h later. In groups

Table 4 Plasma concentrations (μmol litre^{-1}) of amino acids in eight patients receiving amino acid infusion for 1 h before and 1 h of anaesthesia (A), in eight patients receiving amino acids for 2 h before anaesthesia (B), in eight control patients receiving saline solution (C) and in six female volunteers (D). Measurements at the end of amino acid infusion and 2 h later (mean (SEM)). *$P < 0.05$, **$P < 0.01$, ***$P < 0.01$ compared with values after the end of infusion

A, B and D, plasma concentrations for most of the amino acids were significantly above normal immediately after the 2 h amino acid infusions, and higher than in the control patients; the sums of the amino acid concentrations were 4.84, 3.74, 2.21 and 4.96 mmol litre^{-1} groups A, B, C and D, respectively (table 4). In group B, premedicated, and receiving the entire infusion before the onset of anaesthesia, there was a significantly lower maximum sum of amino acid concentrations than the two other amino acid treated groups (A and D) ($P < 0.05$). This difference resulted from significantly reduced concentrations of the individual amino acids, glutamate, arginine, methionine, isoleucine and leucine. Glutamine tended to be higher only in group B compared with the other amino acid treated groups, and remained so 2 h after infusion. Immediately after infusion, the concentration of taurine was significantly higher in group A than in all of the other groups.

At 2 h after the amino acid infusions, individual amino acid concentrations were essentially similar in groups A, B and D, and only moderately increased compared with those in the control patients (group C). The sums of the amino acid concentrations were 2.39, 2.72, 2.31 and 3.17 mmol litre^{-1} in groups A, B, C and D, respectively (ns).

Discussion

Recently, we demonstrated that the thermic effect of amino acids is augmented during general anaesthesia, and that peroperative amino acid infusion thereby prevents the anaesthesia-induced reduction in metabolism and the accompanying postoperative hypothermia [15]. The present data confirm these findings and in addition suggest that amino acid infusion counteracts postoperative hypothermia when given, entirely or partly, before anaesthesia. The anti-hypothermic effect resulted from both increased preoperative heat accumulation and delayed metabolic stimulation immediately after anaesthesia. In addition, heat accumulation in response to amino acids infusion after premedication with lorazepam was greater than normal. Thus when started 1 h after lorazepam premedication, the amino acid infusion increased patients' rectal temperature by approximately 0.3 °C h^{-1}, an increase twice that observed in the volunteers subjected to identical amino acid infusions but not premedicated. This implies that premedication with lorazepam augmented selectively the accumulated part of the extra heat produced during amino acid administration. To our knowledge this response to lorazepam administration has not been reported before. In addition, patients receiving amino acid infusions for 2 h before anaesthesia or for 1 h before and 1 h of anaesthesia exhibited an increase in oxidative metabolism at awakening after anaesthesia of up to 50–60 % above baseline values (before anaesthesia). In the control patients, similarly premedicated and anaesthetized, but receiving saline instead of amino acids, energy expenditure did not increase significantly above baseline, despite vigorous shivering at awakening. Thus the ability of delayed metabolic stimulation, similar to that described recently at awakening immediately after peroperative amino acid infusions [15], was demonstrable also at awakening 30–90 min after the end of amino acid infusions.

Shivering was observed in two of the patients receiving the 2-h amino acid infusion before anaesthesia, but in none of those who had received the infusion for 1 h before and 1 h of anaesthesia. This indicates that prevention of hypothermia was more effective when a peroperative period of infusion was included. This was illustrated further by the finding that the initial decrease in temperature during the first 30 min of anaesthesia was prevented to a significantly greater extent, although not abolished, in patients receiving half of the infusion during anaesthesia. In those patients receiving the entire amino acid infusion before the onset of anaesthesia, the initial temperature change did not differ significantly from that in the control patients receiving saline. However, the considerable amounts of heat accumulated during the 2-h pre-anaesthesia amino acid infusion raised these patients' pre-anaesthesia temperatures to levels which prevented the temperature from reaching true hypothermic levels after operation.

Thus the decrease in temperature during the initial phase of anaesthesia, probably reflecting redistribution of heat within the body [23, 24], was not prevented by pre-anaesthetic infusions of amino acids, and prevented only partly in those patients in whom the infusions were continued during the first hour of anaesthesia. These results confirm our recent finding that peroperative amino acids could not significantly reduce the decrease in temperature until 20 min after the onset of anaesthesia [15].

It is not immediately obvious why amino acid-induced heat accumulation should increase after premedication with lorazepam. Administration of benzodiazepines may interfere with central thermoregulatory control that normally limits the amino acid-induced upward regulation of the resting set point for arterial blood temperature [13–15, 25]. The finding of a significantly reduced resting energy expenditure in all patient groups 1 h after lorazepam is consistent with other reports of reduced metabolism after administration of benzodiazepines [26, 27]. However, the present data indicate that the thermic effect of amino acids was not quantitatively affected, although baseline energy expenditure was depressed by lorazepam.

At awakening, vigorous, generalized shivering occurred in all control patients not receiving amino acids. In spite of the shivering, oxygen consumption was not significantly higher than baseline levels. This finding, similar to that in our previous study [15], confirms that, compared with delayed amino acid-induced thermogenesis, generalized shivering is a relatively weak stimulator of prompt increments in whole body oxidative metabolism in the early postoperative phase.

In awake volunteers, energy expenditure reached its maximum at the end of the 2-h amino acid infusion and then declined slowly. Heat accumulation, however, continued throughout the post-infusion observation period, maximum temperatures being recorded 60–90 min after the infusion. Thus the heat accumulation response to a 2-h amino acid infusion continued for a prolonged period, significant hyperthermia being evident for more than 2 h after the infusion. In patients receiving amino acids before or partly during anaesthesia, postoperative temperatures remained significantly higher than in the control patients during the entire postoperative observation period.

The present findings illustrate that the development of the postoperative hypothermia may be related to anaesthesia-induced suppression of heat production rather than increased heat elimination. The present results indicate that the mechanisms for increased thermogenesis and heat accumulation, when elicited by amino acids, are able to restart after an anaesthesia-induced intermission.

Pulmonary ventilation increased significantly on awakening from anaesthesia in the amino acid treated patients, but not in the control patients. As in our previous study [15], oxygen saturation was normal, indicating that increased oxygen consumption was accompanied by a corresponding increase in ventilation.

In the premedicated patients but not in the volunteers, respiratory exchange ratio increased slightly during amino acid infusion. In male volunteers receiving similar amino acid infusions in earlier studies, the respiratory exchange ratio did not change [14]. It seems difficult to judge if this significant difference represents a true pharmacological effect of lorazepam.

Plasma amino acid concentrations were significantly lower in patients receiving the entire amino acid infusion before anaesthesia compared with those in whom the infusions continued during the first hour of anaesthesia. This might indicate that amino acids infused after the onset of anaesthesia are consumed by the tissues to a lesser extent than those infused before the onset of anaesthesia. However, the sum of the concentrations of all free amino acids was significantly lower also compared with that in volunteers. This might suggest that premedication *per se* could have increased tissue consumption of free amino acids, but additional studies are needed to elucidate this. A significant reduction in plasma concentrations of free amino acids during surgery has been described previously [28].

Anaesthesia-induced postoperative hypothermia is a considerable clinical problem [29] and the present findings may have clinical potential. In suitable patients, i.v. infusion of an amino acid mixture before and during the beginning of anaesthesia for elective and acute surgery is an easy method of preventing anaesthesia-induced hypothermia. Furthermore, compared with the methods of treating hypothermia after operation [30, 31], prevention with amino acids might be beneficial from a metabolic point of view. It has been shown that successful prevention of the development of anaesthesia-induced hypothermia with warming devices, combined with high operating room temperatures, also prevents negative nitrogen balance and catabolism in the postoperative period [3, 31]. Further studies are needed to establish if postoperative nitrogen balance is affected also when the development of postoperative hypothermia is prevented by means of amino acid administration.

The use of amino acids for prevention of anaesthesia-induced hypothermia cannot be recommended for all patients. Treatment should be limited strictly to those who can cope with the possible side effects of an amino acid load. It may be hazardous or harmful for patients with hepatic, renal or metabolic diseases, and should be avoided also in patients with cardiopulmonary insufficiency, who may be unable to cope with the enhanced demands for ventilation and gas transport that occur on awakening. In addition, it should of course be avoided in children < 15 yr until tolerance studies have been performed. With these caveats, amino acid treatment might be a clinically useful and safe method for counteracting the development of anaesthesia-induced hypothermia and its postoperative complications.

Time course of potentiation of mivacurium by halothane and isoflurane in children

O. A. MERETOJA, K. WIRTAVUORI, T. TAIVAINEN AND K. T. OLKKOLA

Summary

We studied 40 children, aged 1–15 yr, to analyse the time course of potentiation of mivacurium produced by halothane and isoflurane. A steady infusion requirement of mivacurium to maintain 90% neuromuscular block was established during thiopentone–alfentanil–nitrous oxide–oxygen anaesthesia. Patients were then allocated randomly to receive 1 MAC end-tidal concentration of either halothane (group Hal) or isoflurane (group Iso) while neuromuscular block was maintained at 90%. Both volatile agents decreased the infusion requirements of mivacurium in an exponential manner in that maximal potentiation occurred only after 30–80 min. Maximal reduction in infusion rate (32% in group Hal and 70% in group Iso; $P < 0.0001$) did not depend on the age of the child but became established sooner the younger the child in the case of isoflurane ($P = 0.002$). (*Br. J. Anaesth.* 1996; **76**: 235–238)

Key words

Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Neuromuscular block, mivacurium. Pharmacodynamics.

Volatile anaesthetic agents reduce the dose requirements of non-depolarizing neuromuscular blocking agents by 0–70% [1–6]. This effect may depend not only on the particular volatile anaesthetic but also on the neuromuscular blocking agent [2, 3]. The potentiation may be a time-dependent phenomenon, even though there are conflicting results [7–9]. In some early studies on the potentiation of neuromuscular blockers by volatile anaesthetic agents, the investigators maintained a steady anaesthetic concentration for more than 1 h before administering the neuromuscular blocker [1], whereas in some recent studies volatile agents were given for less than 15 min [6, 10–12]. This difference in timing may have greatly affected the results of these studies. We designed a study to evaluate the time course of potentiation of mivacurium by halothane and isoflurane in children in order to clarify the issue and to find if the age of the paediatric patient affected the magnitude or time course of this potentiation. Mivacurium was used as the neuromuscular blocker because of its short elimination half-life.

Patients and methods

The study was approved by the Ethics Committee of the Children's Hospital University of Helsinki. After obtaining parental informed consent, we studied 40 ASA I–II patients, aged 1–15 yr. Patients were undergoing elective orthopaedic or general surgery with minimal blood loss and with an anticipated duration of at least 2 h. Patients had no disease or medication known to affect neuromuscular function.

Premedication comprised oral midazolam 0.4–0.5 mg kg^{-1} (maximum dose being 15 mg), 30–60 min before induction. Anaesthesia was induced with thiopentone 4–6 mg kg^{-1} i.v. and alfentanil 50–100 µg kg^{-1} i.v., and inhalation of 66% nitrous oxide in oxygen. The trachea was intubated without the use of neuromuscular blocker. Anaesthesia was maintained with an infusion of alfentanil 100 µg kg^{-1} h^{-1} and 66% nitrous oxide in oxygen. End-tidal carbon dioxide was maintained at 5.0–5.5 kPa and core temperature at > 36 °C throughout the study. For peroperative fluid management, Ringer's solution was infused at a rate of 3–4 ml kg^{-1} h^{-1}. Patients did not require any volume replacement for blood loss.

Neuromuscular function was recorded as an adductor pollicis EMG evoked by supramaximal 2 Hz train-of-four responses at 20-s intervals (Relaxograph, Datex, Finland). The stimulating surface electrodes were attached over the ulnar nerve at the wrist, and the forearm was supported on a dorsal splint with the thumb abducted with a tape. Recording electrodes were attached on the adductor pollicis muscle and on the proximal volar surface of the index finger [13]. Palmar skin temperature was measured and maintained above 34 °C with a warming cover. Routine patient monitoring consisted of ECG, non-invasive arterial pressure, pulse oximetry, end-tidal carbon dioxide and halothane or isoflurane measurement (Capnomac, Cardiocap, Datex).

After calibration of the EMG device and having reached a stable train-of-four response for a minimum of 5 min, a bolus dose of mivacurium 0.1 mg kg^{-1} was administered i.v. and, if needed, this was followed by a second, similar dose to establish > 95% neuromuscular block (depression of the first EMG response from control in the train-of-four series of responses). When the first EMG response recovered to 10% of control, an adaptive closed-loop computer controlled infusion of mivacurium was

commenced to maintain a steady 90% neuromuscular block [14]. Mivacurium was diluted in physiological saline to a concentration of 0.5–2.0 mg ml^{-1} depending on the patient's body weight. The computer program controlling the infusion pump was based on the patient's theoretical pharmacokinetic–dynamic variables and used continuous feedback information from the EMG monitor to adjust the infusion rate at 20-s intervals [14]. Real-time neuromuscular block, current infusion rate and cumulative amount of mivacurium infused were shown on a computer screen and stored in the computer memory.

After a steady state infusion of mivacurium of at least 30 min, a sealed envelope indicating the patient's group was opened, and either halothane (group Hal) or isoflurane (group Iso) was commenced at an inspiratory concentration of 4–5% and then titrated individually to rapidly achieve and maintain an age-adjusted 1 MAC end-expiratory concentration of the volatile anaesthetic agent [15, 16]. At this time the infusion rate of alfentanil was reduced by 50%. Any change in the infusion rate of mivacurium was calculated by the computer. The results were drawn on paper and the cumulative infusion dose of mivacurium was calculated for every 10-min period before and after the start of the volatile anaesthetic agent.

All between-group comparisons were made by Kruskal–Wallis and Mann–Whitney *U* tests, and the data are presented as median (range). Changes in the individual infusion rates of mivacurium for the 10-min epochs were compared by Friedman's two-way analysis of variance. Influence of age within the study groups was examined by linear regression analysis. $P < 0.05$ was regarded as significant.

Results

Groups were matched for age, body weight, amounts of induction agents, duration of anaesthesia and steady infusion rate of mivacurium before the volatile anaesthetic agent was commenced (table 1). One MAC end-tidal concentration of the volatile agent was reached within 2–4 min from opening of the vaporizer in all patients. Figures 1 and 2 show the

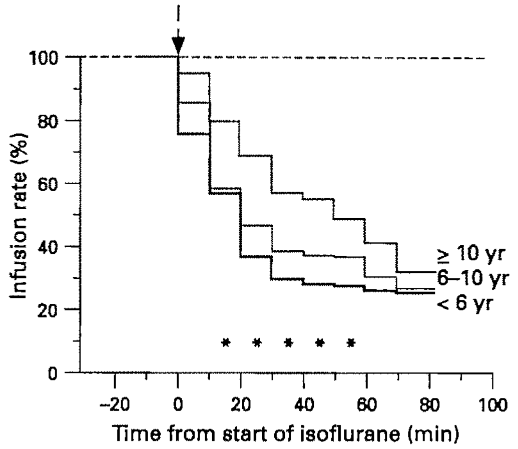

Figure 3 Median infusion rates of mivacurium at 10-min epochs as a percentage of control from commencement of 1 MAC of end-tidal isoflurane (I) in three age groups of children. Potentiation becomes maximal sooner in the youngest children. * $P < 0.05$.

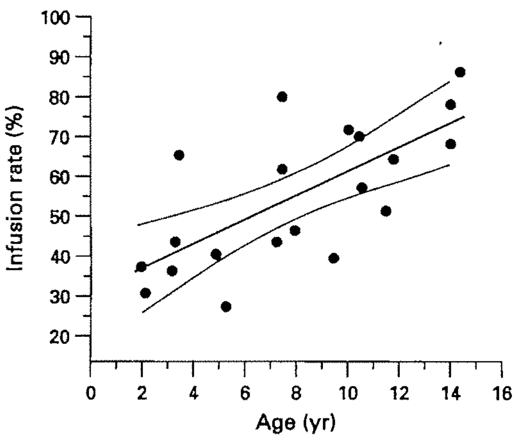

Figure 4 Significant correlation between the age of a child and infusion rate of mivacurium as a percentage of control after 30 min of inhalation of 1 MAC of end-tidal isoflurane. Regression line has been drawn with 95 % confidence intervals ($y = 30+3 \times \text{age}$, $n = 20$, $r = 0.705$, $P = 0.0005$).

individual time course of the effect of halothane and isoflurane on the infusion rate of mivacurium to maintain 90 % neuromuscular block. Within 10 min of inhalation of the selected volatile anaesthetic agent the infusion rate had decreased in group Iso (fig. 2, $P < 0.001$). At all intervals between 10 and 90 min from the start of the volatile anaesthetic, the infusion rate of mivacurium had decreased more in group Iso than in group Hal (table 1).

The maximum effect of halothane or isoflurane in reducing the infusion requirement of mivacurium to maintain 90 % neuromuscular block did not depend on the age of the patient. However, the time course of this potentiation depended on age in group Iso in that maximum potentiation was established sooner the younger the child (time (min) to maximum potentiation $= 32+3 \times \text{age}$ ($r = 0.663$, $P = 0.002$)). Figure 3 illustrates the time course of potentiation of mivacurium by isoflurane in three age groups of children. A similar age-related correlation was not detected in group Hal.

The effect of isoflurane on reducing the requirement for mivacurium was age-dependent within 10–60 min from the start of isoflurane inhalation (r values from 0.515 ($P = 0.02$) to 0.705 ($P < 0.001$)). Figure 4 shows the effect of isoflurane on the infusion requirement of mivacurium in children after 30 min of inhalation of 1 MAC of isoflurane. The younger the child, the smaller was the infusion requirement related to the control 100 % infusion rate before isoflurane (infusion rate (%) $= 30+3 \times \text{age}$ ($r = 0.705$, $P = 0.0005$)). Group Hal did not show similar significant correlations (r values from 0.013 ($P = 0.96$) to 0.227 ($P = 0.34$) within the time interval 10–60 min from the start of halothane inhalation).

Discussion

We have found that potentiation of mivacurium by halothane and isoflurane was strongly time-dependent and took at least 30 min before maximum potentiation was established. In addition, the magnitude of the potentiation did not depend on the age of a child but became established more quickly in younger children when isoflurane was used. We found that conditions for neuromuscular block were unstable for at least the first 30 min of anaesthesia with volatile anaesthesia. This implies that potentiation was decreased with a shorter duration of anaesthesia. Thus it may not be possible to compare data from different studies on neuromuscular blockers if the duration of inhalation anaesthesia is not standardized. Potentiation of mivacurium by isoflurane was greater the younger the child if the duration of anaesthesia was less than 1 h. This suggests that not even a standard duration or concentration of isoflurane guarantees the same degree of potentiation at all ages in children.

There are relatively few studies on the time dependence of the effects of volatile agents on non-depolarizing neuromuscular blockers. Miller, Crique and Eger concluded in 1976 that duration of halothane anaesthesia had no effect on neuromuscular block produced by tubocurarine within 10–160 min [7]. However, their data on cumulative dose–response curves showed that ED_{50} values were greater within 10–20 min than within 40–160 min of halothane anaesthesia (4.6 *vs* 3.1 mg m^{-2}, respectively). Withington and colleagues designed a study with patients as their own controls to evaluate the time course of potentiation of atracurium by enflurane [9]. They found a clear time-dependent reduction in the plasma concentrations of atracurium needed to maintain 90 % neuromuscular block.

We found that halothane and isoflurane produced maximal neuromuscular effect in not less than 30–80 min from onset of administration. Our average infusion rate of mivacurium to maintain 90 % neuromuscular block before the volatile agent was 12 μg kg^{-1} min^{-1} (700 μg kg^{-1} h^{-1}). This rate and its variation are comparable with those described for children to maintain 95 % or 89–99 % neuromuscular block [14, 17, 18]. Brandom and colleagues, and Alifimoff and Goudsouzian found that halothane reduced infusion requirements of mivacurium by 20 % [17, 18]. This reduction in infusion requirements was smaller than that in the present study. However, both of these earlier studies included infusion analysis within the first 15 min of halothane anaesthesia, even though Brandom and colleagues reported that later infusion rates were smaller [18]. Thus it may be that the average infusion rates calculated in these studies did not represent maximal potentiation of neuromuscular block by halothane in children. Our finding of 32% maximal potentiation produced by halothane is very similar to the 36% reduction in vecuronium infusion to maintain 90% neuromuscular block by at least 60 min of halothane anaesthesia in adults [4].

There are no previous paediatric data on infusion requirements for mivacurium during isoflurane anaesthesia. In adults, more than 1 h of isoflurane anaesthesia reduced the bolus dose requirements for tubocurarine by 70% [1] and the infusion requirements for vecuronium to maintain 90% neuromuscular block by 67% [5]. These results for isoflurane-induced potentiation are close to our finding of 70% maximal reduction in infusion requirement of mivacurium during isoflurane anaesthesia. When shorter exposures of isoflurane were studied, less potentiation was observed for mivacurium: 20–30% reduction in dose requirement by 10–15 min of isoflurane [10, 19] and 40% reduction in infusion requirement when infusion data for the first 15 min of isoflurane anaesthesia were included [20]. These results are consistent with our results on the time course of potentiation of mivacurium infusion produced by isoflurane (fig. 2).

A key question in paediatric neuromuscular pharmacology is how infants, children and adults differ in their dose requirements for different neuromuscular blockers [21, 22]. Our study casts doubt on many previous studies on the subject as several studies have been carried out during anaesthesia with unknown duration of volatile anaesthetic agents. Our results indicate that if the timing of the volatile agent has not been controlled, then neuromuscular studies cannot be compared because of unknown potentiation, and comparisons between age groups may be questionable. A serious problem arises if isoflurane has been used; in this case, unstable neuromuscular conditions last for at least 30 min in the youngest children and for even 60 min in older children.

Edrophonium antagonism of intense mivacurium-induced neuromuscular block in children

M. ABDULATIF, A. AL-GHAMDI, M. AL-SANABARY AND M. E. ABDEL-GAFFAR

Summary

We have studied the time course of recovery after administration of edrophonium during intense mivacurium block in children aged 2–10 yr, using thumb acceleration in response to train-of-four (TOF) stimulation. Forty-three children receiving alfentanil, propofol, nitrous oxide, isoflurane anaesthesia and mivacurium 0.2 mg kg^{-1} were allocated randomly to one of three groups. Patients in group 1 ($n = 15$) received edrophonium 1 mg kg^{-1}, 2 min after maximum block (intense block group). At the time of administration of edrophonium in this group, there was no response to TOF stimulation (100% block) and the post-tetanic count was 10.7 (range 0–20). Patients in group 2 received the same dose of edrophonium after 10% recovery of the first twitch (T1) in the TOF (conventional reversal). Patients in group 3 ($n = 13$) recovered spontaneously. All patients developed complete suppression of twitch height in response to the bolus dose of mivacurium. All recovery times were measured from the point of maximum block after mivacurium. Mean time for 25% recovery of T1 (clinical duration) was 3.8 (SD 1.1) min in the intense block group. This was significantly shorter than the conventional reversal (8.3 (2.4) min) and spontaneous recovery (9.2 (3.5) min) groups ($P < 0.001$). The times for 75% and 90% recovery of T1 were shorter in the intense block group (9.4 (2.8), 12.3 (4.2) min) compared with the conventional (13.1 (3.8), 17.3 (4.8) min) and spontaneous recovery (14.9 (4.5), 17.9 (5.2) min) groups ($P < 0.01$). Total recovery time required for 70% recovery of the TOF ratio (T4/T1) was 8.8 (2.4) min in the intense block group. This was significantly shorter than the conventional reversal (11.9 (3.2) min) ($P < 0.05$) and spontaneous recovery (17.1 (4.0) min) groups ($P < 0.001$). Conventional reversal was associated with a shorter total recovery time compared with spontaneous recovery ($P < 0.01$). The recovery index (time interval between T1 25% and 75%) was comparable in groups 1–3 (5.5 (2.0), 4.8 (2.1) and 5.7 (1.4) min respectively). Ten minutes after development of maximum block, the numbers of patients who recovered adequately (TOF ratio 70% or more) were, respectively, 12 (80%), 8 (53%) and 1 (8%) in groups 1–3. We conclude that edrophonium antagonized intense (no response to TOF stimulation) mivacurium-induced block in children, with significant reduction in the recovery times of T1 and TOF ratio compared with conventional reversal and spontaneous recovery. (*Br. J. Anaesth.* 1996; **76**: 239–244)

Antagonists neuromuscular block, edrophonium. Neuromuscular block, mivacurium. Children.

Mivacurium, a short-acting, non-depolarizing neuromuscular blocking agent, has been studied in children to create dose–response curves and to maintain adequate neuromuscular block with a continuous infusion [1–4]. A common finding was that children have increased dose requirements and faster spontaneous recovery than adults under comparable conditions. Recent evidence also suggests that, compared with adults, children have different responses to antagonist-assisted recovery of mivacurium-induced block. When the reversal agents were given at a defined point of recovery, antagonism occurred more rapidly and the dose required to produce an equivalent effect was less in children than in adults [5].

Conventional antagonism of residual non-depolarizing neuromuscular block is usually attempted at the conclusion of surgery after detection of a variable degree of spontaneous recovery. In clinical practice, however, anaesthetic or surgical requirements for neuromuscular block can change suddenly, leaving the anaesthetist in the awkward situation of needing to reverse intense non-depolarizing block, for example failed tracheal intubation after a full paralysing dose of a non-depolarizing neuromuscular blocking agent. Several investigators have tried to antagonize intense non-depolarizing neuromuscular block in adults [6–8] and children [9]. At this depth of block, administration of neostigmine or edrophonium failed to shorten the total recovery time of atracurium- or vecuronium-induced block.

In a recent report [10], we demonstrated that in adults, edrophonium antagonized intense miva-

curium block with a reduction in clinical duration. In the present study, we have examined the time course of recovery after early administration of edrophonium during intense (no response to train-of-four (TOF) stimulation) mivacurium-induced block in children.

Patients and methods

We studied 43 children, ASA I or II, aged 2–10 yr (mean 5.1 yr) and weighing 10–30 kg (mean 17.4 (SD 5.1) kg). All patients were undergoing low risk, short, elective ear and throat surgery, for example tonsillectomy, adenoidectomy or myringotomy. This study was approved by the Hospital Ethics Committee and all parents gave written informed consent. We excluded any patient suffering from cardiac, vascular, respiratory, hepatic, renal or neuromuscular disorders. Patients receiving medications known to affect the activity of plasma cholinesterase enzyme or normal neuromuscular transmission were also excluded.

All patients were premedicated with oral midazolam 0.5 mg kg^{-1} 20–30 min before surgery. In the operating room, an i.v. infusion of 5 % glucose in 0.225 % NaCl solution was given at a rate of 4–6 ml kg^{-1} h^{-1} through a peripheral arm vein. The ECG was monitored continuously and arterial pressure was measured every 5 min using an automatic oscillotonometer (Dinamap). Anaesthesia was induced in all patients with alfentanil 20 µg kg^{-1} and propofol 3–3.5 mg kg^{-1}, and maintained with 1 % inspired concentration of isoflurane and 70 % nitrous oxide in oxygen. Tracheal intubation was performed without the use of neuromuscular blocking agents. Ventilation was controlled to maintain normocapnia (end-tidal carbon dioxide partial pressure 4.6–5.3 kPa). The temperature of the skin overlying the adductor pollicis muscle was monitored and maintained at 32–33 °C. Concentrations of isoflurane, nitrous oxide, carbon dioxide and oxygen saturation were determined continuously by a multiple gas analyser (Capnomac Ultima-SVI, Datex Instrumentation Corporation, Helsinki, Finland).

The ulnar nerve was stimulated supramaximally at the wrist with square pulses of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz repeated every 15 s. An acceleration piezoelectric transducer (Biometer International, Odense, Denmark) was fastened to the volar surface of the distal phalanx of the left thumb using adhesive tape. Free movement during evoked thumb adduction was ensured by fixation of the extended four ulnar fingers by an elastic bandage. Evoked left thumb acceleration, in response to ulnar nerve stimulation and adductor pollicis contractions, was measured using a TOF Guard neuromuscular monitor (Biometer International, Odense, Denmark).

After induction of anaesthesia, a period of 7–10 min was required to stabilize the twitch height recording in all patients. During this period, all patients received the same concentration of isoflurane (1 % inspired). After twitch stabilization, each patient received a single i.v. bolus dose of mivacurium 0.2 mg kg^{-1}. Patients were allocated randomly to one of three groups according to the mode of recovery and timing of antagonist administration. Patients in group 1 ($n = 15$) received edrophonium 1 mg kg^{-1}, 2 min after development of maximum block following mivacurium injection (intense block group). Patients in group 2 ($n = 15$) received the same dose of edrophonium when T1 recovered spontaneously to 10 % of its control value (conventional reversal group). Patients in group 3 ($n = 13$) recovered spontaneously. Atropine 10 µg kg^{-1} was given just before edrophonium to all patients in groups 1 and 2. In the intense block group, if there was no response to TOF stimulation at the time of edrophonium administration, deep block was assessed using post-tetanic stimulation applied to the contralateral ulnar nerve (right arm). The post-tetanic sequence comprised: 50 Hz tetanic stimulation for 5 s, pause 3 s, followed by 1 Hz single twitch stimulation for 20 s. After tetanic stimulation, the number of muscle contractions in response to 1-Hz single twitch stimulation was assessed visually and constituted the post-tetanic count (PTC). A similar current output was used for both hands. PTC was assessed in the contralateral hand to avoid the possible effects of tetanic stimulation on the course of neuromuscular recovery [11, 12].

All information derived from the acceleration transducer, including the duration of the period of no response to TOF stimulation (100 % block), was recorded on a memory card and the following variables were determined from the computer printout of the TOF Guard machine: (1) onset of mivacurium block: time interval between the end of injection of mivacurium and development of maximum block; (2) mivacurium antagonist time: time interval between development of maximum block and edrophonium administration; (3) PTC at the time of administration of edrophonium in the intense block group; (4) time between development of maximum block after mivacurium and recovery of T1 to 25 %, 75 % and 90 % of its control; (5) recovery index (RI): time required for recovery of T1 from 25 % to 75 % of its control; (6) total recovery time: time between development of maximum block after mivacurium and recovery of TOF ratio (T4/T1) to a value of 70 %; (7) T1 and TOF ratio every minute for at least 20 min after development of maximum block; and (8) number of patients in each group who were adequately recovered (TOF of 70 % or more) after 10 min from the development of maximum block after mivacurium.

All patients continued to receive 0.5–1 % isoflurane throughout the investigation. Antagonism was considered adequate at a TOF ratio of 70 %. After tracheal extubation, patients were kept in the recovery room for at least 1 h. Patients were assessed frequently for clinical signs of adequate recovery.

Statistical analyses were performed by one-way analysis of variance (ANOVA) and Student–Newman–Keuls test was used when multiple comparisons between different groups were required. Differences were considered significant at $P < 0.05$.

Table 1 Recovery characteristics (mean (SD)). Mivacurium antagonist time = time interval between maximum block after mivacurium and edrophonium administration; T1 (25), T1 (75) and T1 (90) = time interval between maximum block after mivacurium and recovery of the first twitch in the train of four (T1) to a value of 25%, 75% and 90% of its control; RI = recovery index: time interval between T1 25% and 75%; total recovery time = time interval between maximum block after mivacurium and a train-of-four ratio (T4/T1) of 70%. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ compared with conventional reversal group; ††$P < 0.01$, †††$P < 0.001$ compared with spontaneous recovery group

Group	Mode of recovery	Mivacurium antagonist time (min)	T1 (25) (min)	T1 (75) (min)	T1 (90) (min)	RI (min)	Total recovery time (min)

3	Spontaneous recovery (*n* = 13)	—	9.2 (3.5)	14.9 (4.5)	17.9 (5.2)	5.7 (1.4)	17.1 (4.0)

Results

All patients developed complete ablation of the TOF response (100% block) after administration of the bolus dose of mivacurium. Onset time was comparable in all groups (mean 2.1 (range 1–3.3) min). At the time of antagonist administration, there was no response to TOF stimulation (100% block) in the intense block group with a mean PTC of 10.7 (0–20). Mivacurium antagonism time was significantly shorter in the intense block group compared with the conventional reversal group (table 1, fig. 1).

The times taken for T1 to reach 25%, 75% and 90% of control and for the TOF ratio to recover to 70% were significantly shorter in the intense block group compared with the conventional reversal and spontaneous recovery groups (table 1, figs 1–3). However, the rate of recovery of T1, reflected by the duration of the RI, was comparable in all groups and was not affected by the method of recovery or the timing of edrophonium administration (table 1, figs 1, 2). There was no difference in the times to recovery of T1 between the spontaneous recovery and conventional reversal groups. Total recovery time was shorter in the conventional reversal group compared with the spontaneous recovery group (table 1).

Ten minutes after the development of maximum block, the numbers of patients adequately recovered were 12 (80%), 8 (53%) and 1 (8%) in groups 1–3, respectively.

No patient manifested clinical signs of muscle weakness in the recovery room.

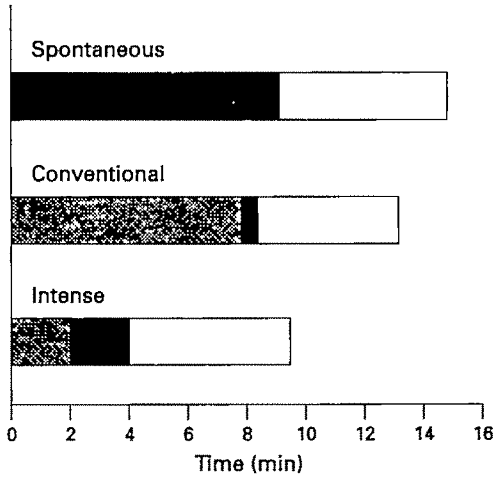

Figure 1 Mean times for recovery of the first twitch of the TOF (T1) after spontaneous or edrophonium-assisted recovery of two levels of mivacurium-induced block. Mivacurium antagonist time (▨) = interval between development of maximum block after mivacurium and edrophonium administration; clinical duration (■) = interval between development of maximum block after mivacurium and recovery of T1 to 25% of its control; recovery index (□) = interval between 25% and 75% recovery of T1. For the two groups of patients who were given edrophonium, the clinical duration includes the mivacurium antagonist time. For all groups, the time required for 75% recovery of T1 is the sum of clinical duration and recovery index.

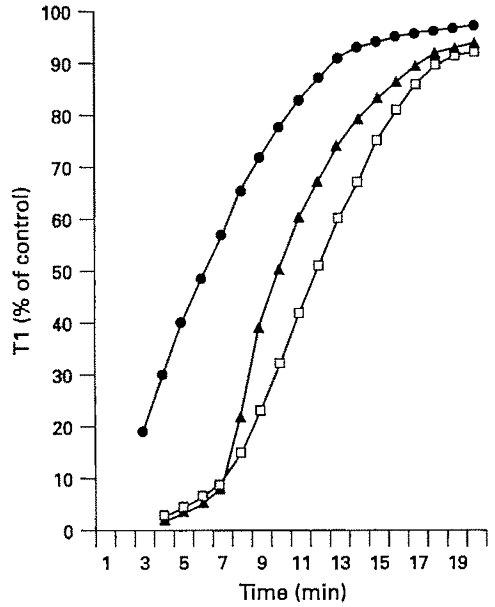

Figure 2 Mean time course and rate of recovery of the first twitch in the train of four (T1) after spontaneous (□) or edrophonium-assisted recovery of two levels of mivacurium-induced block (intense (●) and conventional (▲)). Time zero = when maximum block developed after bolus doses of mivacurium.

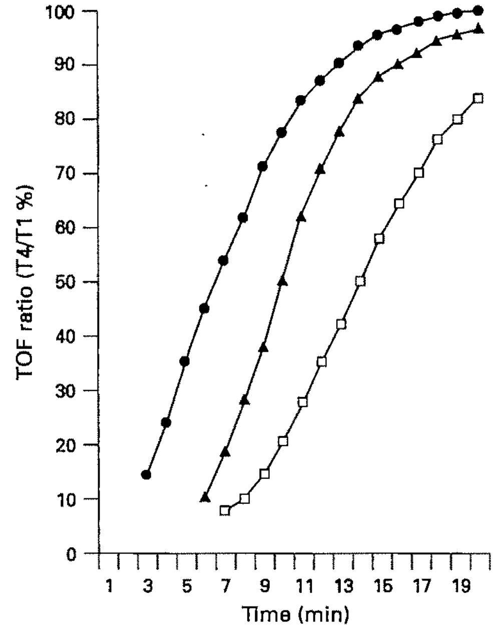

Figure 3 Mean time course and rate of recovery of the train-of-four (TOF) ratio after spontaneous (□) or edrophonium-assisted recovery of two levels of mivacurium-induced block (intense (●) and conventional (▲)). Time zero = when maximum block developed after bolus doses of mivacurium.

Discussion

Mivacurium is unique among non-depolarizing neuromuscular blockers in that it is metabolized by plasma cholinesterase [13]. The activity of butyrylcholinesterase is inhibited by neostigmine [14]. A recent study in children receiving mivacurium for neuromuscular block demonstrated that neostigmine decreased plasma cholinesterase activity by about 85 % but edrophonium had no effect [15]. Earlier reports suggested that spontaneous recovery from mivacurium-induced block may be preferable to the routine use of antagonists [13]. However, later studies showed that in adults, when evidence of spontaneous recovery was present at the end of surgery, antagonism of residual block by neostigmine or edrophonium was superior to spontaneous recovery [16, 17]. The time saved by conventional reversal of mivacurium-induced block in adults is in the range of 7–9 min [13, 16]. In children, when anticholinesterases were given at a twitch height equivalent to 25 % of control during recovery from mivacurium-induced block, the time saved by antagonist-assisted compared with spontaneous recovery of mivacurium block was short and clinically unimportant [15]. This was also the case with conventional reversal in the present study. Compared with spontaneous recovery, conventional reversal was not associated with any time saving with respect to T1 recovery. The difference between total recovery time in the conventional and spontaneous recovery groups was only 5 min. In contrast, edrophonium antagonism of intense mivacurium block was associated with significant reduction in the recovery times of T1 and total recovery time compared with spontaneous recovery. This time saving may be particularly beneficial in a busy day-care facility where the use of mivacurium may be especially indicated.

Our previous experience with antagonism of intense mivacurium block in adults demonstrated that edrophonium reduced the clinical duration but not the total recovery time to a TOF ratio of 70 % [10]. In contrast, in the present study early administration of edrophonium during intense mivacurium-induced block in children was associated with shorter times for T1 and TOF recovery. The times to 25 %, 75 % and 90 % recovery of T1 were reduced compared with conventional reversal and spontaneous recovery. Compared with the adult study, edrophonium antagonism of intense mivacurium block in children was also associated with reduction in total recovery time. Ten minutes after development of maximum block, most patients (80 %) who received edrophonium during intense mivacurium-induced block had recovered adequately (TOF ratio 70 % or more). A general observation was that most of the recovery times of T1 and the TOF ratio in the intense and conventional reversal groups were markedly shorter (50 % or less) in children compared with adults. Spontaneous recovery in children was also faster than antagonist-assisted conventional reversal in adults. The discrepancy between adults and children with respect to recovery after edrophonium antagonism of intense mivacurium block may be an age-related variation in the response to mivacurium, methodological differences, or both, between the two studies.

Spontaneous recovery from neuromuscular blocking drugs is more rapid in children aged 1–10 yr than in adults [18]. This is especially the case with neuromuscular blocking drugs that are largely metabolized in plasma, for example atracurium and mivacurium [19]. An inverse relationship was found between plasma cholinesterase activity and time to first response to TOF stimulation with the use of mivacurium [20–22]. Mean cholinesterase activity in children is about 30% above that in adults [23]. Therefore, faster recovery from the effects of mivacurium in children could be related to increased clearance secondary to changes in the function of its excretory pathways, including plasma esterases. It has been suggested also that the rapid rate of spontaneous recovery from mivacurium-induced block in children may be related to rapid redistribution from the biophase [19]. Beemar and co-workers [24] pointed out that reversal time is determined by two processes: direct antagonism by the anticholinesterase and spontaneous recovery from the effects of the neuromuscular blocking agent, with the latter becoming the major determinant at profound levels of block.

The main differences between the two studies were in the method of recording of the evoked adductor pollicis response and the depth of block at which antagonism was attempted in the intense block group. Force displacement and piezoelectric acceleration transducers were used in the adult and children studies, respectively. A good level of accuracy and correlation between the two types of transducers have been reported by several investigators [25–27]. Therefore, the differences in neuromuscular monitoring equipment do not seem to be sufficient to explain the marked discrepancy between the two age groups.

There was no response to TOF stimulation at the time of administration of edrophonium in the intense block groups in the adult and children studies. However, mean PTC recorded at the time of edrophonium administration in children was 10.7. Mean PTC recorded after the initial detection of post-tetanic response in adults was 3 [10]. This finding confirms the relative resistance of children to mivacurium-induced block and may partly explain the difference in recovery characteristics.

Mangat and co-workers [28] reported that in children aged 2–12 yr, receiving halothane anaesthesia, mean clinical duration of neuromuscular block was 3.2 (range 2.9–3.6) min and 10.25 (9–11.6) min during spontaneous recovery from intubating doses of suxamethonium 1 mg kg^{-1} and mivacurium 0.2 mg kg^{-1}, respectively. The clinical duration of mivacurium-induced block in the spontaneous recovery group in the present study was 9.2 (3.5) min and was comparable with that reported by Mangat and colleagues. However, with early administration of edrophonium during intense mivacurium-induced block, the clinical duration was reduced markedly (3.8 (1.1) min) to approach that of suxamethonium. This finding may be particularly beneficial if the indication for antagonism of intense block was failed tracheal intubation after a bolus dose of mivacurium. In this clinical situation, resumption of adequate breathing may be life saving. Mangat and co-workers [28] demonstrated that in children receiving mivacurium 0.2 mg kg^{-1} and monitored with the use of an acceleration transducer, there was obvious disparity between recovery of respiratory muscles and the adductor pollicis brevis muscle. Spontaneous ventilation was present when T1 had recovered to only 10% of control. This suggests that early antagonism of intense mivacurium-induced block in children can restore spontaneous breathing within 3–4 min after development of maximum block.

An alternative approach to accelerate recovery from intense mivacurium-induced block might be to administer human plasma cholinesterase in the form of either whole blood or a highly purified human plasma cholinesterase preparation. Experimental studies in anaesthetized cats have indicated that antagonism of intense mivacurium-induced block could be achieved with purified human plasma cholinesterase enzyme [29]. However, Bevan [30] pointed out that the use of plasma cholinesterase preparations to antagonize intense mivacurium-induced block in humans may be considered inappropriate as it may increase the risk of serious viral infections related to transfusion of blood products. The results of the present study also indicate that this approach is not only hazardous but unnecessary in children, as edrophonium can antagonize intense mivacurium block within a clinically acceptable recovery time.

Fuzzy logic control of inspired isoflurane and oxygen concentrations using minimal flow anaesthesia

M. CURATOLO, M. DERIGHETTI, S. PETERSEN-FELIX, P. FEIGENWINTER, M. FISCHER AND A. M. ZBINDEN

Summary

In order to evaluate the performance of feedback fuzzy logic control of inspired oxygen and isoflurane concentrations, we studied 30 patients undergoing discectomy for lumbar ($n = 26$) or cervical ($n = 4$) disc herniation. Patients were allocated random to one of two groups: a standard group ($n = 15$) with low flow anaesthesia (1.2–1.3 litre min^{-1}) and manual control of gas concentrations; and a fuzzy group ($n = 15$) with minimal flow (0.5 litre min^{-1}) and fuzzy logic feedback control of gas concentrations. Fuzzy logic control achieved and maintained very accurately the desired isoflurane concentration. Oxygen concentration was controlled more precisely than in the standard group. Delivery and costs of oxygen and nitrous oxide were significantly lower in the fuzzy group ($P < 0.01$). Accumulation of foreign gases was observed in one patient during low flow and in 11 patients during minimal flow anaesthesia. In conclusion, fuzzy logic control of inspired oxygen and isoflurane concentration during minimal flow anaesthesia was reliable and reduced anaesthetic gas delivery and costs. (*Br. J. Anaesth.* 1996; **76**: 245–250)

Key words

Anaesthetic techniques, low flow. Anaesthetics volatile, isoflurane. Computers. Model, computer simulation.

General anaesthesia is usually performed by delivering a fresh gas flow of 1.5–6 litre min^{-1}. As flow is increased, increasing amounts of anaesthetic gases are lost through the escape valve [1]. This increases costs [2] and results in a potential health hazard to personnel [3, 4] and destruction of the ozone layer [5]. Furthermore, a high fresh gas flow results in cold and dry inspired gases that may damage the tracheal epithelium [6].

Closed-circuit anaesthesia minimizes these untoward effects, but cannot be undertaken with many circle systems, mainly because of the high leakage rate, the presence of a hanging bellow which may cause negative pressures in the system and inaccuracy of flowmeters. These restrictions apply to a lesser extent to minimal flow anaesthesia, in which a fresh gas flow of 0.5 litre min^{-1} is delivered. Leakage rates of less than 50 ml min^{-1} can usually be tolerated. Therefore, unlike closed-circuit, minimal flow anaesthesia can be performed with many of the circle systems available. Moreover, it is not necessary to continuously adjust oxygen delivery to maintain the volume of the system.

However, when using this technique, the inspired gas concentrations do not correspond with those in the fresh gas because of mixing with exhaled alveolar gases.

The aim of this study was to evaluate the use of feedback control of inspired oxygen and isoflurane concentration during minimal flow anaesthesia performed by anaesthetists not trained in the minimal flow technique. The system was based on fuzzy logic [7, 8]. In order to compare the performance of the feedback system with a widely used anaesthetic technique, a group of patients undergoing low flow anaesthesia (1.2–1.3 litre min^{-1}) with manual control of inspired oxygen and isoflurane concentrations was also studied.

Patients and methods

We studied 30 ASA I–II patients, undergoing microsurgical fenestration and discectomy for lumbar disc herniation ($n = 26$) or cervical microdiscectomy with interbody fusion ($n = 4$). Patients with coronary artery disease and diabetes mellitus were excluded. The study was approved by the local Ethics Committee and written informed consent was obtained from all patients.

Two groups were studied. In the standard group, anaesthesia comprised the routine method of our department, that is a fresh gas flow of 1.2–1.3 litre min^{-1} and manual control of inspired oxygen and isoflurane concentrations. In the fuzzy group, minimal flow anaesthesia (0.5 litre min^{-1}) was undertaken with fuzzy logic feedback control of inspired oxygen and isoflurane concentrations. The anaesthetist set the desired inspired oxygen and isoflurane

concentrations and the control system adjusted oxygen and isoflurane delivery to achieve and maintain the desired concentrations. The principles of fuzzy logic control are described in the appendix.

Patients were allocated randomly to each of the two groups on an alternate basis. They were premedicated with midazolam 7.5 mg orally, 30 min before induction of anaesthesia. Ringer's lactate 4 ml kg^{-1} was infused rapidly before induction of anaesthesia, followed by 2 ml kg^{-1} h^{-1} before surgery, 4 ml kg^{-1} h^{-1} during surgery and 2 ml kg^{-1} h^{-1} after skin closure. Anaesthesia was performed by staff members, residents or nurse anaesthetists with at least 1 yr experience in anaesthesia; they were not involved in the study but an anaesthetist involved in the study was always present.

After 3 min preoxygenation with 8 litre min^{-1} of 100 vol% oxygen via a face mask, anaesthesia was induced with fentanyl 1 μg kg^{-1} i.v. and thiopentone 5–7 mg kg^{-1}. The trachea was intubated after administration of vecuronium 0.1 mg kg^{-1}. After intubation, 30 vol% inspired oxygen and nitrous oxide, and isoflurane were delivered. The isoflurane concentration was set by the anaesthetist or nurse anaesthetist responsible for anaesthesia, without any influence from the anaesthetist involved in the study, to maintain systolic arterial pressure at 90–140 mm Hg. Vecuronium 1–2 mg was administered to maintain 0–2 responses to train-of-four stimulation of the ulnar nerve, evaluated visually. No other drug was administered until extubation.

After intubation, fresh gas flow was set to 4 litre min^{-1} for 15 min. Flow was then reduced to 1.2–1.3 litre min^{-1} in the standard group and 0.5 litre min^{-1} in the fuzzy group. To prevent accumulation of non-anaesthetic gases, when the cumulative inspired concentration of oxygen, nitrous oxide and isoflurane was lower than 85 vol%, fresh gas flow was increased manually to 10 litre min^{-1} until a total concentration of 97 vol% was achieved. After skin closure, flow was increased to 6 litre min^{-1} in both groups. Residual neuromuscular block was antagonized with neostigmine 2.5 mg i.v. and glycopyrronium 0.5 mg i.v. When four equal responses to train-of-four stimulation were observed, nitrous oxide was discontinued and 100% oxygen was administered. The trachea was extubated as soon as the patient opened the eyes to verbal command.

The period of the study was divided into three parts: induction, from the beginning of preoxygenation to the end of high flow anaesthesia; maintenance, from the beginning of low–minimal flow anaesthesia to the end of surgery; recovery, from the end of surgery to extubation.

We used the Cicero workplace anaesthesia machine (Drägerwerke AG, Germany) (fig. 1). This allows monitoring of ECG, non-invasive arterial pressure (measured every 2.5 min), haemoglobin oxygen saturation using pulse oximetry, and inspired and end-tidal concentrations of oxygen, nitrous oxide and isoflurane sampled at the mouthpiece of the tracheal tube. For safety reasons the same gases were sampled at the mouthpiece of the tracheal tube with an additional monitor (Hewlett Packard M 1025B, Andover, USA). Gas sampled for analysis was returned by connecting the outlet port of both monitors with the expiratory limb of the breathing system.

In the fuzzy group, the anaesthetist or nurse responsible for anaesthesia set fresh gas flow, isoflurane and oxygen concentrations using three dialling buttons on an analogue control panel. The target for inspired oxygen concentration was 30 vol%. The values of inspired concentrations of oxygen and isoflurane set in the control panel represented the desired concentrations, that is the information that the anaesthetist fed into the fuzzy system, which in turn set the flowmeter and vaporizer to achieve and maintain the desired concentrations. The fuzzy logic system controlled a Dräger 19.3 vaporizer driven by an external servo-motor. The servo-motor itself was driven by a PID-controlled amplifier, which in turn was controlled by an electronic interface. The vaporizer driver was built in our laboratory and had been used in a previous investigation [9]. It has an immediate response time without overshooting. The vaporizer and PID control system had been calibrated by gas chromatography. The relation between setting and output was linear with flows of 0.5–5 litre min^{-1}. For safety reasons, the isoflurane concentration in the fresh gas was measured using a Hoyer PAAM gas analyser (Hoyer, Bremen, Germany). Two mass flow controllers (Bronkhorst Hi-Tec, Ruurlo, the Netherlands) were used to supply a precise flow of nitrous oxide and oxygen. They can deliver gas flows from 0.24 to 12 litre min^{-1} with an error of ±0.2% of maximum flow and ±1% of actual flow. Lower gas flows were obtained by intermittently switching off the flows. The Cicero vaporizer and flowmeters were bypassed. Whenever the anaesthetist desired a rapid change of inspired gas concentrations, a "turbo-mode" could be activated. This resulted in a temporary increase in fresh gas flow to 10 litre min^{-1} until the desired concentration was achieved. Whenever the inspired oxygen concentration was less than 26 vol%, the control system temporarily increased the oxygen fresh gas flow to 4 litre min^{-1} until the inspired oxygen concentration reached 26 vol%.

We used two separate static logic fuzzy controllers for oxygen and isoflurane. Both had fixed rules and a cycle time of 10 s. The fuzzy logic controller of inspired oxygen concentration determined the variables of a PID controller. The inputs were the error between desired and measured value, and fresh gas flow. That for inspired isoflurane concentration had three inputs: error between desired and measured values, its integral and fresh gas flow.

In the standard group the anaesthetist or nurse changed the fresh gas flow, and isoflurane and oxygen concentrations using the control panel. The mass flow controllers and vaporizer described above were used. The set values of isoflurane and oxygen concentrations, however, represented the fresh gas concentration as during a normal anaesthetic procedure, the only difference being that the anaesthetist used the panel instead of the vaporizer and flowmeters directly. The target for inspired oxygen concentration during the maintenance period was 30 vol%. In the standard group the "turbo-mode" and the automatic increase in fresh gas flow, when the inspired oxygen concentration was lower than 26 vol%, were not available.

Desired and measured inspired concentrations of oxygen and isoflurane, fresh gas flows, fresh gas concentration of isoflurane and arterial pressure were sampled using the Cicero every 10 s and stored on a IBM compatible computer. The resolution of the measurement of isoflurane concentration was 0.1 vol%.

DATA ANALYSIS

Control of inspired oxygen concentration in the two groups was compared by computing the duration of episodes during which oxygen concentration was between 28 and 32 vol%.

The ability of the fuzzy control to achieve rapidly the desired isoflurane concentration is described as the time needed to change the isoflurane concentration, calculated as follows: time from change of isoflurane concentration to achievement of desired concentration, divided by the difference between previous and desired inspired concentration. Changes of 0.1 vol% were not analysed. Increasing and decreasing concentration of isoflurane were calculated separately. Overshoot was analysed by averaging the maximum difference between measured and desired isoflurane concentration observed during the first 2 min after achieving the desired concentration. The ability of fuzzy logic to maintain the desired isoflurane concentration was described by the frequency distribution of the deviation *(measured − desired) isoflurane concentration,* beginning 2 min after achieving the desired concentration, until the concentration was changed again.

Fresh gas delivery of oxygen and nitrous oxide was recorded using the set point signals of the mass flow controllers, and expressed as the mean of all values of fresh gas flow during each phase (induction, maintenance and recovery) in each patient. Isoflurane delivery was computed by calculating the mean of the product (total fresh gas flow × fresh gas concentration of isoflurane) during each phase in each patient. The fresh gas concentration of isoflurane represented the fraction of gas set at the vaporizer (e.g. 2 vol% = 0.02). Costs of oxygen, nitrous oxide and isoflurane were calculated by multiplying the delivery by the price of each agent.

The stability of anaesthesia was evaluated by computing the duration of episodes during which systolic arterial pressure was between 90 and 140 mm Hg.

Numerical variables in the two groups were compared by Student's t-test when data were distributed normally, otherwise the Mann–Whitney U test was used. Normality was checked by the Wilk–Shapiro test [10]. Categorical variables were analysed by Fisher's exact test. $P < 0.05$ was considered significant. The statistical package used was RS/1, version 4.3.3 (Bolt Beranek and Newman Inc., Cambridge, MA, USA).

Results

Patient characteristics, and duration of surgery and recovery phase are presented in table 1.

During maintenance, the inspired oxygen concentration remained at 28–32 vol% for a longer period in the fuzzy than in the standard group (table 2). In one patient in the fuzzy group and in five in the standard group, the inspired oxygen concentration reached a value of 26 vol%, once in each patient. The minimal value was 24 vol%, which occurred once in both groups. No particular event (e.g. disconnection, airways obstruction, etc.) preceded these decreases in the inspired oxygen concentration. When the critical value of 26 vol% was reached in the fuzzy group, the inspired oxygen concentration was increased automatically by the control system by increasing the oxygen fresh gas flow to 4 litre min^{-1}.

The performance of fuzzy logic control of inspired isoflurane concentration is described in table 3. Inspired isoflurane concentration was changed 125 times during the maintenance period. In 13 instances (nine patients) the desired concentration was achieved by activating the "turbo-mode", in nine instances isoflurane concentration was changed by 0.1% and in 52 the set point was changed again before the desired concentration had been achieved. In eight instances in which the desired concentration was reached, the set point had been increased (decreased) while isoflurane concentration was still decreasing (increasing), and before the previous desired concentration had been achieved. All of these 82 changes in isoflurane concentrations were not analysed. Thus, 26 increases and 17 decreases in inspired isoflurane concentration are shown in table 3. The ability of the system to maintain isoflurane concentration was expressed by the frequency distribution of the deviation (measured − desired) isoflurane concentration, measured 2 min after achieving the desired concentration, until the concentration was changed again. This phase lasted 30 s or less in seven instances, which were therefore excluded from analysis. Thus the ability of the system to maintain isoflurane concentration was analysed in 36 instances (table 3).

Table 1 Patient characteristics, and duration of surgery and recovery phase (median (25–75 percentiles))

	Standard group	Fuzzy group	*P*
Sex (M/F)	7/8	8/7	ns
Age (yr)	41 (35–51)	43 (37–49)	ns
Weight (kg)	72 (60–77)	77 (67–86)	ns
Preop. systolic arterial pressure (mm Hg)	120 (110–130)	130 (120–140)	< 0.05
Duration of surgery (min)	75 (58–109)	85 (52–117)	ns
Recovery phase (min)	17 (14–24)	16 (13–22)	ns

Table 2 Control of inspired oxygen (O_2) concentration in the two groups during the maintenance phase. The duration of episodes during which the concentration was between 28 and 32 vol%, below 28 and above 32 vol% are expressed as percentage of duration of the maintenance period. Median (25–75 percentiles) values are presented

	Standard group	Fuzzy group	*P*
O_2 concn 28–32 vol% (% of duration of period)	64% (47–94%)	82% (76–91%)	< 0.01
O_2 concn < 28 vol% (% of duration of period)	2% (0–10%)	1% (0–4%)	ns
O_2 concn > 32 vol% (% of duration of period)	23% (5–42%)	17% (9–20%)	< 0.05

Table 4 Stability of anaesthesia in the two groups during the maintenance period, evaluated by stability of systolic arterial pressure (SAP). The duration of episodes during which SAP was between 90 and 140 mm Hg, less than 90 and greater than 140 mm Hg are expressed as percentage of duration of the maintenance period. Median (25–75 percentiles) values are shown. No statistically significant difference between the two groups

	Standard group	Fuzzy group
SAP 90–140 mm Hg (% of duration of period)	97% (91–100%)	96% (91–100%)
SAP < 90 mm Hg (% of duration of period)	0% (0–0%)	0% (0–0%)
SAP > 140 mm Hg (% of duration of period)	1% (0–7%)	2% (0–9%)

The duration of episodes during which systolic arterial pressure was less than 90 or greater than 140 mm Hg is presented in table 4. Table 5 shows the inspired concentrations, delivery and costs of gases.

In four patients in the fuzzy group, 4–29 min after the beginning of minimal flow, low volume of gas in the circuit was detected by the alarm system. The volume was restored by briefly pressing the oxygen flush button. Median body weight of these patients was higher than that of the other 11 patients (87.5 and 73 kg, range 65–100 and 61–90, respectively), but the difference was not statistically significant.

In 11 patients in the fuzzy group and in one in the standard group, fresh gas flow had to be set at 10 litre min^{-1} for 45–60 s, because of high concentration of non-anaesthetic gases. This occurred in the fuzzy group for the first time 18–41 min after the beginning of minimal flow (median 22 min) and a total of 1–5 times in different patients. Within the fuzzy group, median body weight of the 11 patients who required high flow was higher than that of the other four patients (79 and 70 kg, range 62–100 and 61–77, respectively), but the difference was not statistically significant.

Discussion

We have assessed the performance of fuzzy logic control of inspired oxygen and isoflurane concentrations during minimal flow anaesthesia. As only the research anaesthetists involved in the study (and not those performing clinical anaesthesia) were familiar with the minimal flow technique, we could not study a control group of patients undergoing minimal flow anaesthesia with manual control of

Table 3 Description of the performance of fuzzy logic feedback control of inspired isoflurane concentration during the phase of minimal flow. n = Number of increases (n_1) and decreases (n_2) of isoflurane concentrations and of phases during which isoflurane concentration was not changed (n_3), which were included in the analysis. The first two variables describe the ability of the feedback system to achieve the desired isoflurane concentration, whereas the last one describes the ability to maintain the desired concentration, beginning 2 min after achieving the desired concentration, until the concentration was changed again. The 13 occasions when the "turbo-mode" was manually activated are not included. Median (25–75 percentiles) values are presented

Time to increase inspired isoflurane concn (s vol%$^{-1}$) ($n_1 = 26$)		700 (540–850)
Overshoot after increasing isoflurane concn (vol%) ($n_1 = 26$)		0.1 (0.1–0.2)
Time to decrease inspired isoflurane concn (s vol%$^{-1}$) ($n_2 = 17$)		660 (360–1130)
Overshoot after decreasing isoflurane concn (vol%) ($n_2 = 17$)		0.1 (0.1–0.2)
Frequency distribution of the deviation (measured – desired) isoflurane concentration when isoflurane concentration was not changed ($n_3 = 36$)	$\leqslant -0.3$ vol%	0%
	-0.2 vol%	3%
	± 0.1 vol%	94%
	$+0.2$ vol%	3%
	$\geqslant 0.3$ vol%	0%

Table 5 Median (25–75 percentiles) values of inspired concentration, delivery and costs of inhaled agents in the two groups during the maintenance period. Inspired concentrations were recorded every 10 s, and the values shown represent medians and 25–75 percentiles of the mean values calculated for each patient

	Standard group	Fuzzy group	*P*
Inspired concentration			
Oxygen (vol%)	30 (29–31)	30 (30–31)	ns
Isoflurane (vol%)	0.9 (0.8–1.2)	0.9 (0.7–1.1)	ns
Delivery			
Oxygen (litre min^{-1})	0.59 (0.52–0.64)	0.34 (0.31–0.40)	< 0.01
Nitrous oxide (litre min^{-})	0.94 (0.80–1.07)	0.32 (0.25–0.39)	< 0.01
Isoflurane (ml gas min^{-1})	18.2 (13.3–25.7)	16.2 (9.4–18.5)	ns
Costs			
Oxygen (Swiss Francs h^{-1})	0.05 (0.05–0.06)	0.03 (0.03–0.04)	< 0.01
Nitrous oxide (Swiss Francs h^{-1})	1.02 (0.86–1.15)	0.35 (0.27–0.42)	< 0.01
Isoflurane (Swiss Francs h^{-1})	6.40 (4.67–9.04)	5.68 (3.30–6.49)	ns
Total (Swiss Francs h^{-1})	7.36 (5.59–10.17)	6.02 (3.65–6.98)	< 0.05

inspired gas concentrations. However, although the standard group does not represent a true control group because of the different fresh gas flow used, it allows comparison of fuzzy controlled anaesthesia with a widely used anaesthetic technique. However, control of inspired oxygen and isoflurane concentrations is easier during low flow than during minimal flow anaesthesia and therefore, the experimental design was biased *against* the fuzzy logic system.

One may wonder why we developed a system controlling inspired isoflurane concentration, as most anaesthetists think in terms of end-tidal concentration and previous studies have shown good control of end-tidal concentration with other feedback algorithms [11, 12]. One reason is that end-tidal feedback control may not be feasible or reliable in some situations, such as during spontaneous ventilation or anaesthesia in children with a face mask. Furthermore, unlike the aforementioned studies [11], we used minimal flow anaesthesia, and the desired concentration was not fixed during operation [12] but changed according to anaesthetic requirements. During minimal flow anaesthesia there is usually a large difference between end-tidal and fresh gas concentrations and the response of end-tidal concentration to changes in the fresh gas concentration is very slow. Because of these features it is difficult to develop an automatic system controlling end-tidal concentration by directly adjusting fresh gas concentration. We therefore developed a system to control inspired concentration, which can be used later in the control of end-tidal concentration in a cascade feedback system.

The control of inspired oxygen concentration in the fuzzy group was more precise than in the standard group, in spite of the lower fresh gas flow delivered (table 2).

Fuzzy logic control achieved and maintained the desired inspired concentration of isoflurane during minimal flow anaesthesia very accurately: overshoot was not observed and the desired concentration (±0.1 vol%) was maintained for 94% of the time (table 3). The long time needed to achieve the desired concentration (table 3, which does not include the occasions when the "turbo-mode" was activated) was the result of the very low fresh gas flow delivered. The anaesthesia machine, Physioflex (Physio BV, Hoofddrops, The Netherlands), allows feedback control of gas concentrations during closed-circuit anaesthesia. The presence of a turbine hastens gas mixing. This allows rapid achievement of inspired concentration when the fresh gas concentration is changed, thereby facilitating development of a feedback system. Such a technical feature is not available in conventional anaesthetic systems, such as that used in our study.

It was not possible to compare the two groups in terms of control of inspired isoflurane concentration, as in the standard group the anaesthetist controlled the fresh gas concentration and was not requested to specify a desired inspired concentration. This was avoided because the anaesthetists were used to adjusting the vaporizer to reach a desired end-tidal concentration or a pharmacological effect, but not a specific inspired concentration.

During minimal flow anaesthesia a decrease in the volume of gas in the anaesthetic system was observed in four patients, probably because of persisting nitrous oxide uptake of the patient. Accumulation of foreign gases in the circuit, a well-known disadvantage of closed-circuit anaesthesia [13], occurred frequently. Accumulation of nitrogen causes dilution of oxygen and anaesthetic agents. High blood concentrations of acetone after long-term closed-circuit anaesthesia increase the incidence of postoperative nausea and vomiting [14]. Methane accumulation can disturb infrared analysis of volatile anaesthetics [15]. Frequent flushing of the system with high fresh gas flows to remove foreign gases partially offsets the advantages of the minimal flow technique. Flushing of the anaesthesia circuit rapidly removes nitrogen and methane from the system [13], but does not decrease blood concentrations of acetone during long-term closed-circuit anaesthesia [14]. At present it is not known if blood concentrations of acetone increase during minimal flow anaesthesia.

Unlike oxygen and nitrous oxide delivery, isoflurane delivery in the fuzzy group was not significantly lower than in the standard group ($P = 0.06$). This was in part the result of frequently flushing the system with high flows because of accumulation of foreign gases. This factor would have had a lower impact if we had studied longer operations, as nitrogen elimination from the body decreases with time. Furthermore, as a result of different individual requirements, inspired isoflurane concentration and delivery varied greatly (table 5). Therefore, the expected small difference in isoflurane delivery between low flow and minimal flow anaesthesia might only be detected by studying a large patient population.

Appendix

INTRODUCTION TO FUZZY LOGIC CONTROL

Fuzzy logic

By *crisp objects* we imply that something is of a yes-or-no-type rather than a more-or-less-type. For instance, in a set of individuals we may say "John is a boy". But if we wish to define body height and decide that a person of 170 cm or more is tall and the rest are short, we have to classify Peter, who is 169.9 cm, as "short", and John, who at 170 cm is only 1 mm taller, as "tall". In order to avoid this dilemma fuzzy logic is introduced, that is the boundaries of a set are *fuzzy* instead of *crisp*. This makes it possible to classify an element as being *to a certain degree* a member of a set, by introducing membership function values between 0 and 1 [16]. It should be noted that fuzzy sets and continuous membership functions are closer to human thinking.

Fuzzy logic and probability theory are different. Probability theory deals with questions such as: "there are 30 white balls and 70 black balls in a bag. I draw a ball without looking. Is this ball black?" Answer: "with a 70% probability it is." Fuzzy logic deals with questions such as: "I have a grey ball. Is this ball black?" Answer: "we assign the value 0 for absolute white and 1 for absolute black. The statement "the ball is black" has a truth value of, say, 0.2 (the ball is light grey)". Thus fuzziness does not imply randomness [17].

Knowledge-based control

The classical controller calculates the input signal of the plant to be controlled based on the difference between a reference signal and the actual output of the plant. For instance, a so-called PID controller considers the error, its integral and its range of change in computing the input signal for the "plant" according to a mathematical formula. It is also possible to design a controller which uses a knowledge base to perform the controller function. For instance, it is possible to control the speed of a car so that it is constant with the following set of rules:

IF (speed is very low) THEN (accelerate sharply)
IF (speed is low) THEN (accelerate slightly)
IF (speed is high) THEN (decelerate)
IF (speed is very high) THEN (brake)
IF (speed is low AND road is uphill) THEN (accelerate sharply)

The values for "very low", "low", etc., have to be defined crisply.

Fuzzy control

A fuzzy controller is a knowledge-based controller where the variables have fuzzy instead of crisp values. It consists of: a *fuzzification module* which performs linguistic classification of variables; a *fuzzy knowledge-base* similar to a regular knowledge-base as in the car example containing rules of the type IF (error is slightly negative) THEN (fresh gas concentration is small); an *inference engine* which uses the fuzzy rules in the knowledge-base to produce a fuzzy control output based on control inputs; and a *defuzzification module* which determines a crisp control value from a fuzzy control value.

LABORATORY INVESTIGATIONS

Methylprednisolone inhibits endotoxin-induced depression of contractile function in human arteries *in vitro*

I. TSUNEYOSHI, Y. KANMURA AND N. YOSHIMURA

Summary

We have studied the effect of methylprednisolone on endotoxin-induced depression of contractile function in human gastroepiploic arteries. Endotoxin diminished the contractile response to noradrenaline in both the presence and absence of endothelium. This attenuation began after 4 h and reached a maximum after 10 h of endotoxin exposure. The cGMP content of endotoxin-treated rings was approximately seven-fold higher than in control rings. These endotoxin-mediated responses were blocked by L-NAME and methylene blue. These data indicate that the main cause of vascular hyposensitivity to noradrenaline was massive generation of nitric oxide. Pretreatment with methylprednisolone at concentrations (2.0–20.0 μg ml^{-1}) similar to those achieved in plasma after therapeutic administration dose-dependently inhibited these endotoxin-mediated responses. These data support the concept that pharmacological administration of methylprednisolone has the potential to prevent endotoxin-induced depression of the contractile response to noradrenaline seen in endotoxaemic shock. (*Br. J. Anaesth.* 1996; **76**: 251–257)

Key words

Polypeptides, endotoxin. Arteries. Hormones, glucocorticoid. Sympathetic nervous system, catecholamines.

Prolonged exposure of arterial tissue to endotoxin or to any of several cytokines has been shown to suppress its normal contractile response to cathecholamines [1]. Recent reports suggest that α adrenergic desensitization in inflammatory conditions is not mediated by changes in the number of receptors or their affinity for agonists, but may be caused by excessive production of endogenous nitric oxide (NO) [2–4]. There is strong evidence that inhibition of NO production may reverse the vascular hyporeactivity to pressor agents seen in patients with septic shock [5, 6].

NO is synthesized from the amino acid L-arginine through activation of NO synthase (NOS). It increases cellular levels of guanosine 3′, 5′-cyclic monophosphate (cGMP) which then induces vasorelaxation [7]. Two distinct forms of NOS have been identified in vascular tissues; these have been designated "constitutive" and "inducible" forms of NOS. Constitutive NOS (cNOS) is present in endothelium and contributes to vasodilatation under normal conditions [7]. The inducible form (iNOS) is expressed mainly in smooth muscle cells several hours after stimulation by a variety of stimuli, such as endotoxin or cytokines, and induces the production of a large amount of NO [8–10]. This raises the possibility that this enzyme may play a major role in vascular desensitization to pressor agents, leading to profound hypotension during inflammatory conditions. For this reason, pharmacological manipulation of iNOS might prove clinically useful in mitigating the abnormal vascular reactions in such conditions.

Expression of iNOS was found to be inhibited by the protein synthesis inhibitor cycloheximide [9]. Aminoguanidine, which is a nucleophilic hydrazine, was found to inhibit the relaxation of arterial rings from endotoxin-treated rats [11]. Moreover, iNOS requires tetrahydrobiopterin as a co-factor and inhibition of tetrahydrobiopterin synthesis was found to abolish endotoxin-induced NOS production in rat aortic smooth muscle cells [12]. However, cycloheximide has several severe side effects and other potentially useful drugs are as yet unlicensed and have still to undergo formal toxicological studies.

Glucocorticoids have also been shown to inhibit the expression of iNOS in several species [9, 13], indicating that the use of glucocorticoids may be useful in suppressing iNOS activity in humans. Although it has been suggested that glucocorticoids may have the capacity to prevent or suppress the development of cardiovascular collapse [14], not enough is known about the usefulness of glucocorticoids as potential inhibitors of the overproduction of NO evoked by endotoxin in human arteries.

In the present study, we investigated the effect of methylprednisolone, at concentrations within the range of serum concentrations reached during i.v. infusion of methylprednisolone 30 mg kg^{-1} in adult humans, on endotoxin-induced attenuation of noradrenaline-induced contraction in human gastroepiploic arteries *in vitro*. In addition, we measured cGMP concentrations in the same vascular tissues as an index of NOS activity.

Materials and methods

PREPARATION

With the approval of the Ethics Committee of Kagoshima University School of Medicine, the omentum was resected from the stomach of each of 42 patients immediately after gastrectomy had been performed under general anaesthesia; each omentum was stored in oxygenated Krebs solution. The patients, who were all less than 70 yr old (mean 65.8 (range 38–69) yr) and who had suffered from gastric cancer, had no vascular disease or other complications. Furthermore, none had taken any anti-inflammatory drugs, such as aspirin or steroids, or vasoactive drugs before operation. Thirty minutes or less after the omentum had been resected, the gastroepiploic arteries were isolated in a dissecting chamber filled with Krebs solution, and fat and connective tissue removed carefully under a binocular microscope. Two vascular rings of length 2 mm were prepared from each artery for tension recording. One ring was carefully denuded of endothelium by inserting a small forceps into the lumen and gently rolling the ring backwards and forwards in the dissecting chamber. The lack of a functional endothelium was confirmed by the absence of endothelium-dependent relaxation of noradrenaline-induced contractions normally induced by acetylcholine 1×10^{-5} mol litre^{-1}.

ORGAN CHAMBER EXPERIMENTS

Mechanical activity in the human gastroepiploic arterial rings was assessed using a strain gauge (UL-100GR, Minebea, Tokyo) with the ring in a tissue bath filled with Krebs solution bubbled continuously with 95 % oxygen: 5 % carbon dioxide. The bath had a volume of 1.0 ml and the temperature of the solution was maintained at 37 °C. Krebs solution was infused continuously at a rate of 1 ml min^{-1} by a pump (Perista pump SJ-1211, ATTO, Tokyo) from one end of the bath and aspirated simultaneously by a water pump from the other. Resting tension was set at a value (20 mN) shown by the length–tension relationship to allow maximal active tension to be induced by noradrenaline 1.0 µmol litre^{-1}. The contractile response was measured as the maximum amplitude of the phasic response read from the pen recorder, and the response at the beginning of the experiment was normalized as a value of 1.0 for each ring. After 2 h of equilibrium in Krebs solution, noradrenaline 1.0 µmol litre^{-1} was applied to the vascular rings for 7 min every 30 min. After the amplitude of the contraction induced by noradrenaline 1.0 µmol litre^{-1} had become constant, endotoxin 10 µg ml^{-1} (lipopolysaccharide) was applied to the tissue by adding it to the Krebs solution. Other agents (N^G-nitro-L-arginine-methyl ester (L-NAME), methylene blue) were infused in Krebs solution so that the tissue was exposed to the dose indicated in the text. To determine the effect of glucocorticoid on endotoxin-induced attenuation of the evoked contractions, methylprednisolone was added in Krebs solution at a concentration of 20.0, 2.0 or 0.2 µg ml^{-1}. The arterial rings were immersed in medium containing methylprednisolone just after being prepared and throughout the experiment. To study the effect of glucocorticoids on ongoing endotoxin-induced attenuation, methylprednisolone 20.0 µg ml^{-1} was added 6 h after the start of some experiments, when attenuation induced by endotoxin had already begun.

ASSAY OF CGMP

After fat and connective tissue had been removed, gastroepiploic arterial rings (weight 30–50 mg) with the endothelium intact were allowed to equilibrate for 1 h in beakers containing Krebs solution bubbled with 95 % oxygen: 5 % carbon dioxide. One of the rings was then incubated with endotoxin 10 µg ml^{-1} and the other with either endotoxin 10 µg ml^{-1} with methylprednisolone 20 µg ml^{-1}, endotoxin 10 µg ml^{-1} with L-NAME 1 mmol litre^{-1} or endotoxin 10 µg ml^{-1} with methylene blue 10 µmol litre^{-1}. Approximately 12 h later, the phosphodiesterase inhibitor, 3-isobutyl-1-methylxanthine (IBMX) 100 µmol litre^{-1} was added to each preparation, 30 min before cGMP determination and then each ring was homogenized rapidly in a glass homogenizer. cGMP was extracted from the homogenate using trichloroacetic acid and the amount of cGMP in the extract measured using a cGMP enzyme immunoassay kit (Amersham International, Little Chalfont, UK).

SOLUTIONS

The composition of the Krebs solution was as follows (mmol litre^{-1}): Na^+ 137.4, K^+ 5.9, Mg^{2+} 1.2, Ca^{2+} 2.6, HCO_3^- 15.5, $H_2PO_4^-$ 1.2, CL^- 134.4 and glucose 11.5. All solutions contained indomethacin 10 µmol litre^{-1} to prevent the effects of prostanoids and L-arginine 200 µmol litre^{-1} as a substrate for NOS. They were bubbled with 95 % oxygen: 5 % carbon dioxide which adjusted the pH to 7.4. As contamination with endotoxin may be assumed to be substantial even in solutions made using distilled water, we used sterilized glassware and endotoxin-free water obtained from Ostuka Chemical Co. (Tokyo).

The chemicals used were: noradrenaline bitartrate, acetylcholine chloride, endotoxin (lipopolysaccharide: *E. coli* 055: B5), methylprednisolone, methylene blue, L-arginine and indomethacin, all form Sigma Chemical Company (St Louis, MO, USA), and N^G-nitro-L-arginine methyl ester (L-NAME) from Funakoshi (Tokyo, Japan).

STATISTICAL ANALYSIS

Results are expressed as mean (SD). The amplitude of the contraction induced by noradrenaline at the start of the experiment was normalized as a relative tension of 1.0 for each ring. Differences between the endotoxin-treated and methylprednisolone-treated groups were evaluated by analysis of variance. If significant differences were detected, Student's unpaired *t* test was used. To evaluate the dose-

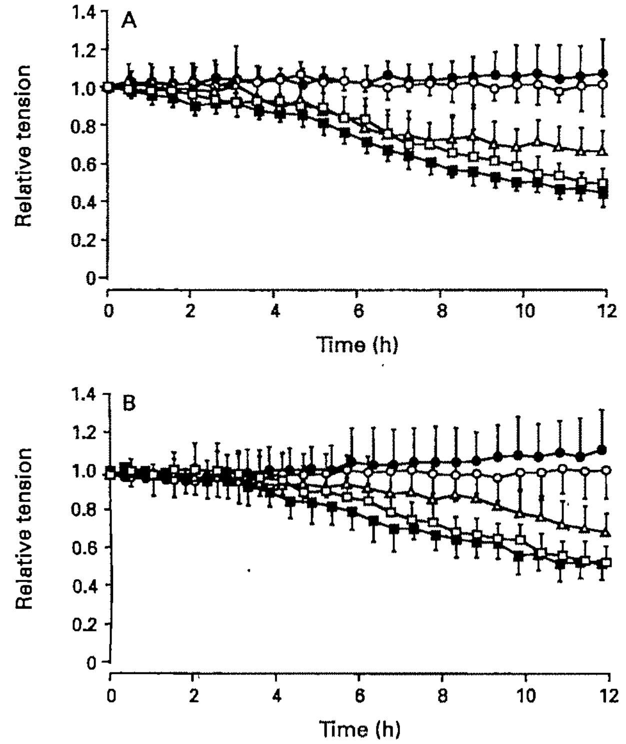

Figure 1 Effect of endotoxin 10 µg ml^{-1} on noradrenaline 1.0 µmol litre^{-1}-induced contractions and concentration-dependent effects of methylprednisolone on endotoxin-induced attenuation in endothelium-intact (A) and endothelium-denuded (B) rings from human gastroepiploic (mean, SD). Noradrenaline 1.0 µmol litre^{-1} was applied to the vascular rings for 7 min every 30 min over a 12-h period. The maximum amplitude of noradrenaline-evoked contraction at the start of the experiment was normalized as a relative tension of 1.0 for each arterial ring. Methylprednisolone treatment was begun before, and continued throughout application of endotoxin (which was begun at time 0). A: Noradrenaline-induced contraction with (■) or without (●) endotoxin 10 µg ml^{-1} treatment in endothelium-intact arteries. In endotoxin-treated rings, methylprednisolone prevented the attenuation of contraction in a dose-dependent manner (20.0 µg ml^{-1} (○), 2.0 µg ml^{-1} (△), 0.2 µg ml^{-1} (□)) ($n = 7$). B: Similar experiment in endothelium-denuded arteries (details as in (A)).

dependency of the effect of methylprednisolone, regression analysis was conducted with replication and Spearman rank correlation coefficients. Probabilities less than 5% ($P < 0.05$) were considered significant.

Results

EFFECT OF ACETYLCHOLINE ON NORADRENALINE-INDUCED CONTRACTION

When a functional endothelium is present, but not when it is absent, noradrenaline-induced contractions can be relaxed by acetylcholine. In our rings with intact endothelium, acetylcholine 1×10^{-5} mol litre^{-1} relaxed the noradrenaline 1.0 µmol litre^{-1}-induced contraction to 58.8 (8.3)% ($P < 0.01$, Student's unpaired t test, $n = 42$; the amplitude of the noradrenaline 1.0 µmol litre^{-1}-induced maximal contraction being normalized as 100%). On the other hand, in our endothelium-denuded rings, acetylcholine-induced relaxation was not observed (95.0 (5.2)%, $n = 42$).

EFFECT OF ENDOTOXIN ON NORADRENALINE-INDUCED CONTRACTIONS

After 2 h equilibration of the tissues in Krebs solution, noradrenaline 1.0 µmol litre^{-1} was applied for 7 min every 30 min. After the response to noradrenaline 1.0 µmol litre^{-1} had become stable, endotoxin 10 µg ml^{-1} was applied for 12 h. In the absence of endotoxin, the amplitude of contraction induced by noradrenaline 1.0 µmol litre^{-1} in endothelium-intact rings remained stable for more than 12 h (after 12 h, 1.05 (0.17) times the initial maximal contraction, $n = 7$). Similarly, the amplitude of noradrenaline-induced contractions in endothelium-denuded rings was stable for 12 h (after 12 h, 1.16 (0.20), $n = 7$). Endotoxin 10 µg ml^{-1} gradually attenuated the noradrenaline-induced contractions over a long time period, both in endothelium-denuded and endothelium-intact rings (fig. 1). Thus after 12 h treatment with endotoxin 10 µg ml^{-1}, the amplitude of contraction was 0.43 (0.07) in endothelium-intact rings ($n = 7$) and 0.53 (0.09) in endothelium-denuded rings ($n = 7$). Table 1 shows the effect of 12-h exposure to endotoxin on the contraction induced by noradrenaline 1.0 µmol litre^{-1}, and the effect of an inhibitor of NOS, L-NAME 1.0 mmol litre^{-1} and that of an inhibitor of guanylate cyclase, methylene blue 10 µmol litre^{-1}. Endotoxin-induced relaxation was abolished by administration each of these drugs.

Table 1 Attenuation of noradrenaline-induced contraction induced by 12-h exposure to endotoxin and its inhibition by L-NAME or methylene blue (MB) (mean (SD)). The initial maximal contraction induced by noradrenaline is given the value 1.0. ** $P < 0.01$ compared with value after 12 h of noradrenaline-induced contractions (Student's t test)

	Relative tension		
		12.5 h after	
Sample ($n = 7$)	12 h after	L-NAME (1 mmol litre^{-1})	MB (10 µmol litre^{-1})
Control			
Endothelium intact	1.05 (0.17)	1.06 (0.21)	1.05 (0.13)
Endothelium denuded	1.16 (0.20)	1.28 (0.17)	1.15 (0.24)
Endotoxin 10 µg ml^{-1} added			
Endothelium intact	0.43 (0.07)	0.92 (0.17)**	1.03 (0.15)**
Endothelium denuded	0.53 (0.09)	0.91 (0.14)**	0.92 (0.13)**

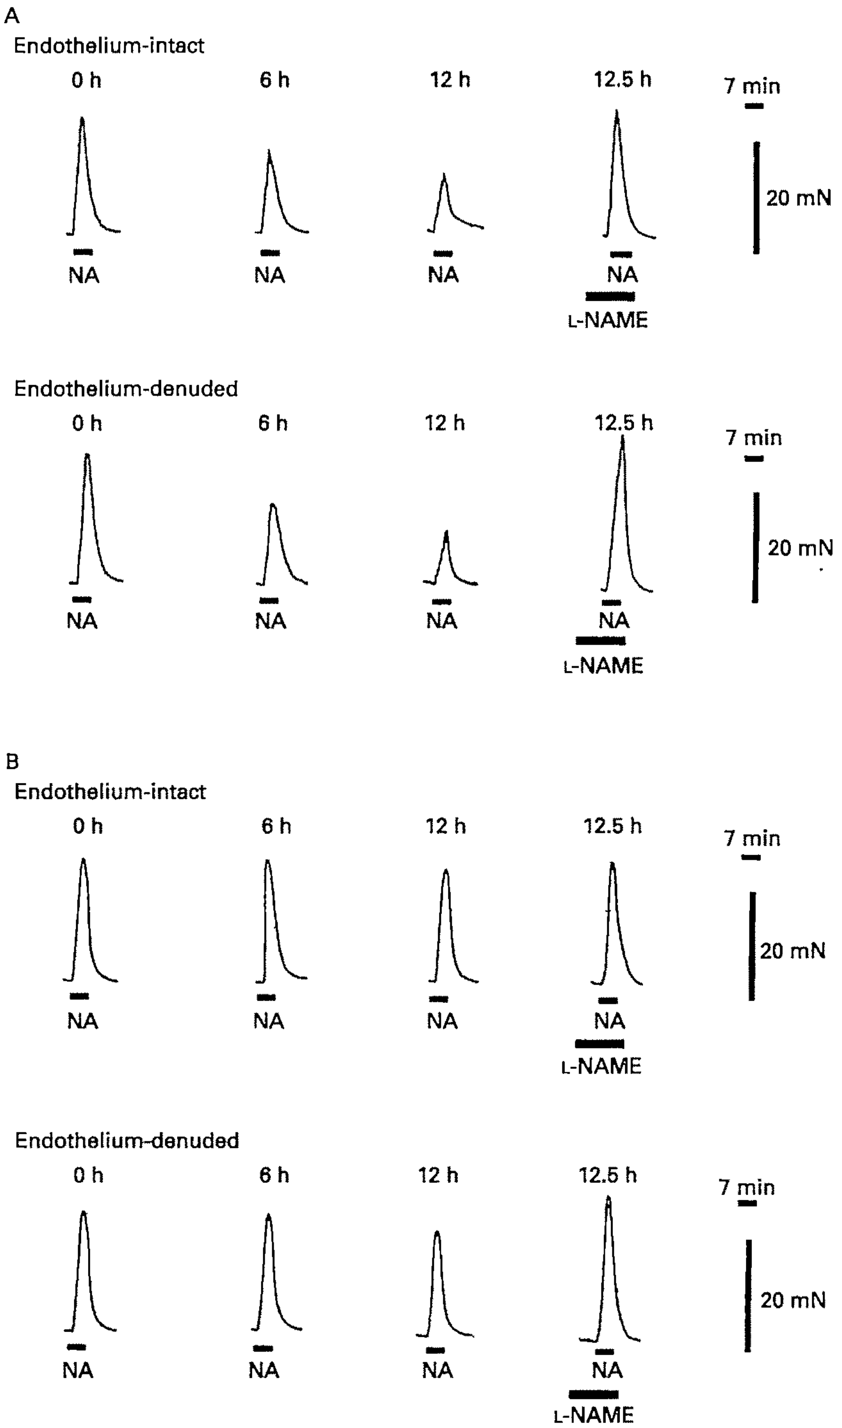

Figure 2 Typical examples of the effect of methylprednisolone 20 μg ml^{-1} on endotoxin 10 μg ml^{-1}-induced attenuation of contraction in endothelium-intact and endothelium-denuded rings from human gastroepiploic arteries. Noradrenaline (NA) 1.0 μmol $litre^{-1}$ was applied to the vascular rings for 7 min every 30 min over a 12-h period. A: Effect of endotoxin 10 μg ml^{-1} (begun at time 0) on contractions induced by NA 1.0 μmol $litre^{-1}$. Endotoxin-treatment was continued for 12 h and then L-NAME 1.0 mmol $litre^{-1}$ was applied. B: Effect of methylprednisolone 20 μg ml^{-1} on the attenuation of contraction induced by endotoxin 10 μg ml^{-1}. Methylprednisolone was present throughout the 12-h incubation.

EFFECT OF METHYLPREDNISOLONE ON ENDOTOXIN-INDUCED ATTENTION OF CONTRACTION

Endotoxin-induced inhibition of noradrenaline-induced contraction was reduced or abolished by methylprednisolone in a dose-dependent manner. Figure 2 shows typical records of contractions induced by noradrenaline 1.0 μmol $litre^{-1}$ in endotoxin 10 μg ml^{-1}-treated rings and in rings treated with both endotoxin and methylprednisolone 20 μg ml^{-1}. After treatment with endotoxin had been in progress for 6 or 12 h, the noradrenaline-induced contraction was reduced significantly in both endothelium-intact and endothelium-denuded rings. This inhibition was prevented in both types of ring when methylprednisolone 20 μg ml^{-1} was present in the medium throughout the experiment, the amplitude of contraction remaining constant for 12 h

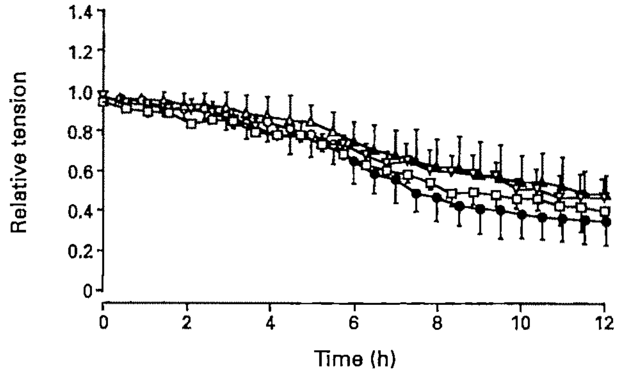

Figure 3 Effect of delayed application of methylprednisolone 20 μg ml^{-1} on the attenuation of contraction induced by endotoxin 10 μg ml^{-1} (mean, SD). Endotoxin 10 μg ml^{-1} was applied to endothelium-intact (○, □) and endothelium-denuded (△, ▽) rings from human gastroepiploic arteries for 12 h. In some experiments, methylprednisolone 20 μg ml^{-1} was present for the second 6-h period only in endothelium-intact (●) and endothelium-denuded (▲) arterial rings ($n = 7$).

(fig. 1). In contrast, a low concentration of methylprednisolone (0.2 μg ml^{-1}) in Krebs solution had no effect on the attenuation induced by endotoxin (endothelium-intact arteries: 0.48 (0.09); endothelium-denuded arteries: 0.54 (0.09), both after 12 h, $P > 0.05$). A moderate concentration of methylprednisolone (2.0 μg ml^{-1}) had a preventative effect that was slight but significant (endothelium-intact arteries: 0.65 (0.14); endothelium-denuded arteries: 0.68 (0.11), both after 12 h, $P < 0.05$). The corresponding values with methylprednisolone 20.0 μg ml^{-1}, showing complete inhibition, were: endothelium-intact arteries: 1.04 (0.21); endothelium-denuded arteries: 0.99 (0.15) ($P < 0.01$). On the other hand, in control rings not treated with endotoxin, methylprednisolone did not modify the contractions evoked by noradrenaline 1.0 μmol litre^{-1} (endothelium-intact arteries: 1.10 (0.21); endothelium denuded arteries: 1.02 (0.14), both after 12 h, $P < 0.05$).

Figure 3 shows the effect of methylprednisolone 20.0 μg ml^{-1} when applied to endotoxin-treated rings for only 6 h, beginning 6 h after the start of the experiment. Such delayed addition of methylprednisolone 20 μg ml^{-1} was ineffective after the attenuation induced by endotoxin commenced. At the end of 12 h, the relative tension values induced by noradrenaline were: endothelium-intact rings, 0.46 (0.12) without methylprednisolone, 0.40 (0.11) with methylprednisolone ($P > 0.05$, $n = 7$); endothelium-denuded rings, 0.51 (0.08) without methylprednisolone, 0.52 (0.10) with methylprednisolone ($P > 0.05$, $n = 7$).

CHANGES IN CGMP CONTENT OF VASCULAR TISSUES

We chose to measure the cGMP content of rings with intact endothelium as their status was probably closer to that of normal blood vessels. Endotoxin greatly increased the amount of cGMP in rings with intact endothelium cut from human gastroepiploic arteries. The measured amounts of cGMP were: before exposure to endotoxin, 223.2 (78.6) fmol/mg protein and after 12 h application of endotoxin, 1628.6 (790.0) fmol/mg protein ($P < 0.05$, $n = 6$). This endotoxin-induced increase in cGMP content was blocked by methylene blue 10 μmol litre^{-1} (cGMP content 52.9 (74.1) fmol/mg protein, $P > 0.05$, $n = 6$) and by L-NAME mmol litre^{-1} (cGMP content 256.3 (66.8) fmol/mg protein, $P > 0.05$, $n = 6$). The increase in cGMP content in endotoxin-treated rings was also prevented by continuous application of methylprednisolone 20 μg ml^{-1} (cGMP content 339.7 (197.5) fmol/mg protein, $P > 0.05$, $n = 6$) (fig. 4).

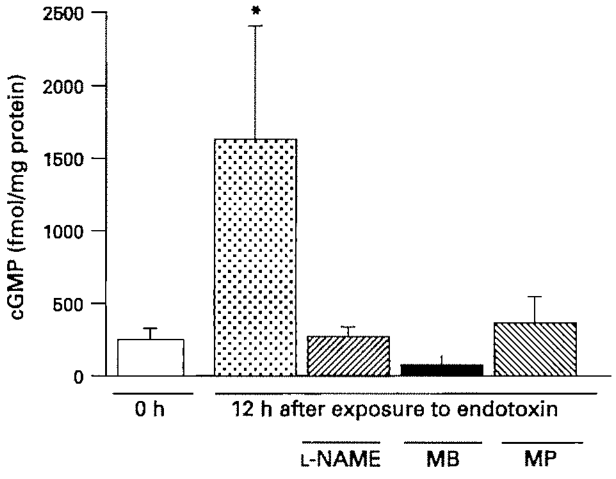

Figure 4 Effects of endotoxin 10 μg ml^{-1} (□), N^G-nitro-L-arginine methyl ester (L-NAME) 1.0 mmol litre^{-1} (▨), methylene blue (MB) 10 μmol litre^{-1} (■) and methylprednisolone (MP) 20 μg ml^{-1} (▧) on cGMP content in human gastroepiploic arteries with the endothelium intact (mean, SD). One of a pair of rings was incubated with endotoxin 10 μg ml^{-1} and the other with either endotoxin 10 μg ml^{-1} with MP 20 μg ml^{-1}, endotoxin 10 μg ml^{-1} with L-NAME mmol litre^{-1} or endotoxin 10 μg ml^{-1} with MB 10 μmol litre^{-1}. Each inhibitor was applied for 1 h before and throughout the experiment. IBMX 100 μmol litre^{-1} was added to each solution 30 min before cGMP determination ($n = 7$). $^*P < 0.05$ compared with amount of cGMP at 0 h.

Discussion

These results demonstrate that pretreatment of isolated human vascular tissues with methylprednisolone inhibits, in a concentration-dependent manner, endotoxin-evoked depression of the contractile response to noradrenaline. This inhibitory activity of methylprednisolone was seen at concentrations as low as those achieved in plasma after therapeutic administration.

In the present study, contractions of arteries elicited by noradrenaline remained more or less constant throughout each experiment in the absence of endotoxin, suggesting that the anaesthetics and neuromuscular blocking drugs used did not alter vasoreactivity under the experimental conditions. On the other hand, in arterial rings exposed to endotoxin 10 μg ml^{-1}, noradrenaline-induced contractions showed a gradual decrease in tension both in the presence and absence of endothelium for several hours after the initial exposure to endotoxin. These results indicate that noradrenaline-induced contraction, which occurs via stimulation of α adrenergic receptors, was depressed easily by endotoxin. Moreover, this effect of endotoxin was reversed by the NO inhibitor, L-NAME, and by the guanylate cyclase inhibitor, methylene blue. Consequently, we conclude that endotoxin evoked massive production of NO, and thus diminished the contractile response to noradrenaline. A similar conclusion was reached after experiments on rat aortic rings incubated with endotoxin [15]. Indeed, it was demonstrated that the reduced sensitivity to catecholamines in endotoxaemic rats was caused by overproduction of endogenous NO [2, 3].

Endotoxin also increased the intracellular concentration of cGMP in our arterial tissues, the content of cGMP in rings treated with endotoxin for 12 h being about seven-fold greater than that in control rings. This effect of endotoxin was blocked also by both methylene blue and L-NAME. These studies with inhibitors indicate that the increase in cGMP evoked by endotoxin may result from activation of a soluble form of guanylate cyclase. Previous reports by other authors have also indicated that release of NO from vascular walls activates guanylate cyclase, producing cGMP [2–4]. The mechanisms by which cGMP evokes smooth muscle relaxation have been studied [16–18] and the conclusion reached that increased smooth muscle cGMP content is associated with a reduced intracellular calcium level. Thus, these results may explain the endotoxin-induced reduction in sensitivity to noradrenaline, as the response of vascular smooth muscle to α adrenergic agents is dependent mainly on the concentration of free Ca^{2+} in the myoplasm [19].

The interaction of glucocorticoids with cardiovascular tissue has been shown to play an important role in cardiovascular function. It is clear that they potentiate the constrictor response of vascular smooth muscle to catecholamines after several days' exposure, although there is still no consensus on the exact mechanisms involved [20–22]. Interestingly, recent data have indicated that glucocorticoids inhibit induction of iNOS in vascular tissue and reduced the sustained hypotension induced by endotoxin in animal experiments [23–25]. In our experiment, the glucocorticoid methylprednisolone, partially or completely prevented, in a dose-dependent manner, endotoxin-induced diminution of the contractile response to noradrenaline. Additionally, accumulation of cGMP in endotoxin-treated human arterial rings was blocked by the presence of methylprednisolone 20.0 $\mu g\ ml^{-1}$. These results suggest that methylprednisolone suppressed endotoxin-induced expression of iNOS and thus prevented endotoxin-induced depression of sensitivity to noradrenaline in human arteries.

These preventative effects of methylprednisolone in our *in vitro* study support the concept that the drug could be used as a therapeutic agent for reducing or preventing the vascular hyporeactivity mediated by endotoxin. The concentration of methylprednisolone in human plasma has been reported to reach a maximum of 20.0 $\mu g\ ml^{-1}$ just after i.v. administration of 30 $mg\ kg^{-1}$ in the adult human. There was a rapid decrease for approximately 12 h (12 h after injection, the concentration was about 2.0 $\mu g\ ml^{-1}$) and then a slower decline over the next 12 h [26]. In our experiments, methylprednisolone 20.0 $\mu g\ ml^{-1}$ completely prevented the attenuation of contraction induced by endotoxin and methylprednisolone 2.0 $\mu g\ ml^{-1}$ reduced it slightly but significantly, while 0.2 $\mu g\ ml^{-1}$ had no effect. The effective concentration of methylprednisolone used here correlates well with the serum concentrations found during the first 12 h after i.v. infusion of methylprednisolone 30 $mg\ kg^{-1}$ in the adult human. Therefore, i.v. infusion of 30 $mg\ kg^{-1}$ should have the potential to prevent or reduce the desensitization to cathecholamines induced by endotoxin in human arteries.

However, in our study, when methylprednisolone 20 $\mu g\ ml^{-1}$ was given after the attenuation of contraction induced by endotoxin had started, it failed to elicit inhibition. A recent report by Marumo and colleagues [27] has suggested that, in rat cultured smooth muscle cells, glucocorticoids act by directly inhibiting expression of the iNOS gene, rather than by reducing its enzymatic activity (which persists for several days) [9]. These results suggest that when iNOS has been induced sufficiently by endotoxin, methylprednisolone might be unable to exert a preventative effect on the generation of NO, which would already have been raised by the increase in iNOS. Therefore, methylprednisolone might need to be given before, or shortly after, exposure to the bacterial pathogens that produce endotoxin.

Glucocorticoids have powerful immunosuppressive and anti-inflammatory actions and are pharmacologically useful in the treatment of various diseases. However, there is still considerable controversy on their use in the treatment of severe sepsis or septic shock [28, 29]. A recent report has warned of the possible adverse effects of methylprednisolone in the treatment of critically ill patients [30]. On the other hand, a massive dose of methylprednisolone 30 $mg\ kg^{-1}$ repeated once after 4 h if the patient remains unstable has been reported to reduce early mortality and circulatory failure in septic shock [28]. Our results support the concept of a beneficial effect of methylprednisolone on the vascular hyporeactivity associated with immunologically released NO in humans. Moreover, as recent data provide strong evidence of an important role for mediators such as cytokines or phagocytic cells in the pathogenesis of septic shock [31], the desirable immunosuppressive effects of glucocorticoids may include a direct cytotoxic action. Thus the efficacy of glucocorticoids in septic conditions may depend on the balance between their protective and deleterious roles.

Central nuclei and spinal pathways in feedback inhibitory spinal cord potentials in ketamine-anaesthetized rats

S. DENDA, K. SHIMOJI, M. TOMITA, H. BABA, T. YAMAKURA, H. MASAKI, H. ENDOH AND S. FUKUDA

Summary

It has been suggested that heterosegmentally activated slow positive potentials (HSP), recorded from the spinal cord of rat and humans, are feedback inhibitory potentials. The present study was carried out to define ascending and descending spinal tracts and the sites of central nuclei involved in the production of these HSP, and the effects of ketamine on these central nuclei. The spinal cords in ketamine-anaesthetized rats were transected to determine the ascending and descending tracts involved in the production of hindpaw (HP) and forepaw (FP) HSP, respectively. Lesions of the brain at various levels were performed stereotactically during ketamine anaesthesia. Dorsal one-third resection of the cord at the T8–9 level did not affect HSP significantly, while contralateral lesion of the dorsal two-thirds of the cord decreased FP–HSP but not HP–HSP during ketamine. Bilateral transection of the ventral one-third of the cord abolished both HSP. Ablation of the cerebral cortex, cerebellum, thalamus, midbrain and pons did not affect HSP significantly. However, transection of the middle medulla decreased, while transection of the most caudal part of the medulla completely abolished both HSP. Ketamine decreased HSP even in the medulla–spinal cord preparation and the segmental slow positive wave in spinalized animals. In ketamine-anaesthetized rats, ascending and descending spinal tracts involved in the production of HP–HSP and FP–HSP are located bilaterally in the ventrolateral quadrant and in the contralateral lateral funiculus and ventrolateral quadrant, respectively. Principal central nuclei feeding back HSP might be situated diffusely in the medulla down to the caudal part. Ketamine is suggested to suppress these inhibitory feedback potentials predominantly at, and partly even below, the level of the medulla. (*Br. J. Anaesth.* 1996; **76**: 258–265)

Key words

Anaesthetics i.v., ketamine. Monitoring, evoked potentials. Spinal cord, evoked potentials. Rat.

In addition to segmentally evoked spinal cord potentials (segSCP) produced in the segmental dorsal surface of the cord, slow positive potentials (heterosegmentally evoked slow positive potentials (HSP)) can be recorded from the heterosegmental dorsal surface of the spinal cord by peripheral skin nerve stimulation in ketamine-anaesthetized rats [1–3], and by large nerve trunk stimulation close to the cord in conscious humans [4, 5]. Physiological and pharmacological features of these HSP suggest that they reflect feedback inhibitory activities via supraspinal structures [1–3], probably feedback primary afferent depolarizations (PAD) [3], providing an important feedback control system of sensory transmission, including pain. Such HSP might also provide a tool for studying the mechanism of transcutaneous electric nerve stimulation (TENS) or electroacupuncture [5].

Previous studies in ketamine-anaesthetized rats [2] suggested that central nuclei which send the feedback impulses to the spinal cord thereby producing HSP may exist in more than one brain structure, as latencies of HSP showed inter-individual variation.

The present study was undertaken to determine the central feedback nuclei involved in the production of HSP, and also the sites of the effects of ketamine on these HSP in preparations containing principal central nuclei. We also tested which portions of the cord were responsible for ascending and descending tracts producing HSP in a specially designed preparation.

Materials and methods

Approval of the Institutional Committee on Animal Experimentation was obtained, and the institutional guidelines for use of laboratory animals were observed and followed during the present study.

The experiments were carried out in 23 adult male rats, weighing 300–350 g. The anaesthetic and surgical procedures were the same as those reported in previous studies [1–3] except for the additional experimental brain and spinal cord lesions. After i.p. injection of ketamine hydrochloride 120 mg kg^{-1} with atropine sulphate 0.1 mg kg^{-1}, a tracheal tube

was introduced through a tracheostomy and connected to a Harvard animal ventilator. Tidal volume and frequency of 50–60 b.p.m. were adjusted to maintain a normal $P\text{E}'_{CO_2}$ of 4.5–5.3 kPa, monitored by a capnograph via a small polyethylene tube (250 μm in diameter) introduced into the orifice of the tracheal tube. The animals were paralysed by i.v. injection of pancuronium 0.2 mg kg^{-1} h^{-1}.

The left femoral artery and vein were cannulated to monitor arterial pressure, sample blood and permit infusion of Ringer's lactate solution 4 ml kg^{-1} h^{-1} with ketamine 30 mg kg^{-1} h^{-1} and fresh blood from another ketamine-anaesthetized rat when bleeding exceeded 20 ml kg^{-1} (25–30 % of total blood volume). Arterial blood samples (0.1 ml) were obtained at the time of cannulation, at the middle of the experimental procedures, at termination of the experiment and occasionally at the time of mass bleeding (in three cases) to check the adequacy of blood gases and packed cell volume (PCV). Three animals received 22–30 ml kg^{-1} of fresh blood even though evoked potentials were not affected significantly. Bleeding was controlled by light pressure with cotton or by gel foam. Blood loss was determined by the dilution method. Blood was sucked into a glass bottle through a stainless tube or absorbed in the gauze. Blood in the gauze was washed gently by a saline solution in another bottle, and PCV of the diluted blood in these two bottles was measured.

Preliminary experiments with electroencephalography (EEG) and somatosensory evoked potentials from the brain and spinal cord showed no significant changes with stable arterial pressure over a period of several hours during infusion of ketamine [1–3] at a rate which was adequate to suppress behavioural responses of the rat to surgical incision without administration of a neuromuscular blocker. A cannula was inserted also through a small skin incision into the urinary bladder to allow monitoring of urine volume. The electrocardiogram was monitored continuously through needle electrodes inserted into the s.c. tissue of the thorax. Rectal temperature was maintained at 37.0–38.0 °C by a homeothermic blanket system.

The animals were mounted on a stereotactic frame, and laminectomies were carried out on C5–6 and T8–L1 vertebrae to expose the cervical and thoracolumbar cord. The head was also secured gently in a stereotactic frame by ear bars.

Flexible ball-tip electrodes (Ag–AgCl) were placed gently on the cervical (C5) and lumbar (L5) cord surfaces by the floating method (spring mounting) at the midline. Reference electrodes were fixed to nearby bones. A needle electrode was placed at the left preorbital area with the reference electrode at the left ear to monitor the EEG and brain evoked potentials. The right forepaws and hindpaws were stimulated electrically by a stimulator (Nihon Kohden SEN-7103) through a constant current isolation unit at 1 Hz with silver–silver chloride needle electrodes (150 μm in diameter, 10 mm in length) inserted s.c. into the vestigial thumb and fourth digit on the forepaw and the first and fifth toes on the hindpaw. Stimulus (square wave monophasic pulse, 0.1 ms) intensity was adjusted to 2.5–10 × threshold strength (1.3–1.7 to 13–17 V) for the segmental negative cord dorsum potential (N1) so that it constantly produced slow positive waves in all animals. The same stimulus was applied to both fore- and hindpaws using a switch box. The stimulus intensity used was monitored in a preliminary study by recording the nerve action potentials from the sural nerve at the end of the experiments, and verified to evoke Aβ and Aδ fibre action potentials but not C fibre action potentials (13–17 V) [2]. All potential changes were averaged ($n = 50$) by a computer (ATAC 1300, Nihon Kohden) and plotted on an X–Y plotter.

The peak amplitudes of N1 and P2 components in the segSCP and those of HSP were measured from the background activity (see tables 1 and 2). The background activity (the pre-response baseline) was recorded in response to forepaw (FP) or hindpaw (HP) stimulation at the subthreshold strength in each experiment.

All evoked potential recordings were conducted under stable haemodynamics (mean arterial pressure (MAP) 70–105 mm Hg; heart rate (HR) 380–450 beat min^{-1}). A slight transient increase and an increase followed by a decrease in MAP and HR were sometimes observed during skin incision and spinal cord lesion, respectively, but not during electrical stimulations.

EXPERIMENT I: SPINAL CORD LESIONS

As shown in figure 1, transection of the spinal cord at the thoracic level destroyed the ascending tract for HP–HSP and that of the descending tract for FP–HSP, which was described originally by Villanueva and colleagues in their study on diffuse noxious inhibitory control (DNIC) [6]. Pilot studies showed that electrical coagulation methods extended substantially beyond the limit of the lesion to the surrounding tissues on histological examination. Therefore, we prepared small pieces of razors to insert perpendicularly from the dorsal surface of the spinal cord, and fixed the cord by injecting 10 % formalin i.v. at the end of the experiment for histological examination. Six pieces of razors were inserted into the cord, one by one, at the T8–T9 level, as shown in figure 1, 0.5 mm apart, from the caudal to the rostral sites after eliminating the arachnoid and pia maters with a fine pincette under light microscopy, and the evoked potentials were recorded following each additional lesion. The ventrodorsal axis (diameter) of the spinal cord was measured in preliminary experiments in five rats and the depth of insertion was determined as shown in figure 1. Differences between the stereotactically induced lesions and histological examination were within the range of 0.05 mm.

EXPERIMENT II: BRAIN LESIONS AND EFFECTS OF KETAMINE

After craniotomy and exposure of cerebral and cerebellar cortices, suction of brain tissue throughout the cerebral cortex and whole cerebellum was carried

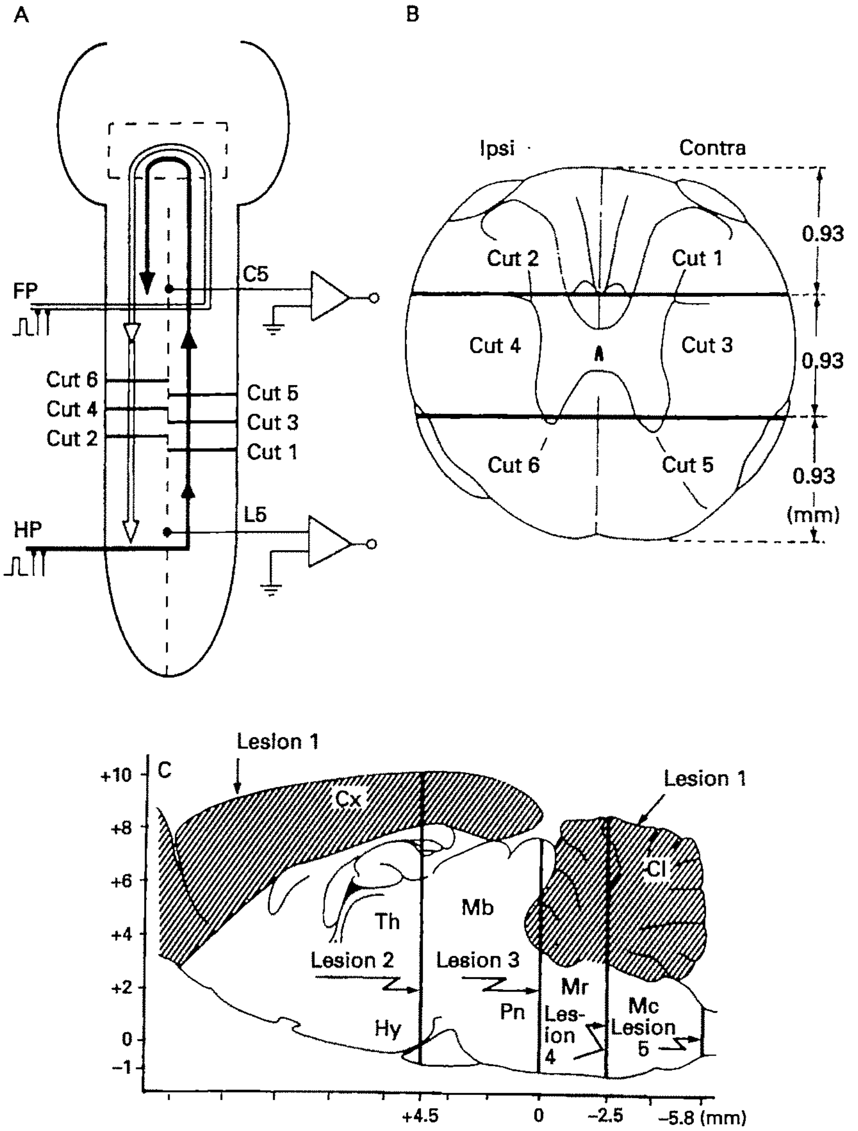

Figure 1 Schematic (A) and stereotactic (B, C) representations of experimental procedures. A: The spinal cord was transected at the T8–9 level so that the afferent tract for HSP evoked by hindpaw (HP) stimulation and the descending tract for that evoked by forepaw (FP) stimulation were blocked, respectively. B: The spinal cord was hemisected from the contralateral dorsal one-third (cut 1) to the ipsilateral ventral one-third, from caudal to rostral, 0.5 mm apart, as shown in (A). Small pieces of razors were inserted stereotactically, one by one, from the dorsal surface of the cord at 0.93-mm steps. C: The brain lesion was carried out as described in the text from lesion 1 to lesion 5. Lesion 1 = resection of whole cerebral cortex and cerebellum; lesion 2 = resection between the thalamus, including the hypothalamus and the midbrain, at AP+4.5, according to the atlas of Paxinos and Watson [7]; lesion 3 = transection between the pons and medulla oblongata at AP±0; lesion 4 = transection at the middle part of the medulla at AP−2.5; lesion 5 = transection at the most caudal part of the medulla oblongata at AP−5.75 mm.

out with the assistance of a bipolar blood coagulation apparatus under a stereotactic microscope.

The thalamus with the underlying hypothalamus was resected at the level of AP+4.5 mm (fig. 1) using a plate with a sharpened edge, leaving the most part of the midbrain according to the stereotactic brain map of Paxinos and Watson [7]. The midbrain and pons were severed at the level of AP±0 mm, leaving the medulla intact. Transection was performed at the level of the middle medulla, AP−2.5 (fig. 1). Finally, the most caudal part of the medulla was transected at the level of AP−5.75 mm, thus separating the whole medulla from the spinal cord (fig. 1) [7]. In the latter part of the experiment (in six of 14 animals), the third and fourth transections were conducted initially, as the first to third procedures did not affect HSP.

The third and fourth procedures sometimes caused transient hypotension and arrhythmia (two and one in the third and fourth sections, respectively) which recovered fully within 2–5 min with Ringer's lactate solution, or blood, or both, and no pharmacological intervention.

Evoked potential recordings were performed at least 30 min after each step of brain lesion, as the evoked potentials sometimes showed transient suppression and subsequent recovery 10–25 min after lesion. During this 30-min waiting period, Ringer's lactate solution with or without blood or bicarbonate was infused rapidly when MAP decreased to less than 60 mm Hg or when base excess decreased to less than -5 mmol litre^{-1}, respectively.

All surgical procedures were carried out under ketamine anaesthesia. Preliminary experiments showed that even the lesions down to the pons did not change HSP significantly which, however, decreased when the lesion was made at the middle of the medulla (the fourth procedure). Thus after resection of the midbrain and pons (the third procedure), ketamine infusion was stopped for 30 min to test its effect on HSP in the medulla–spinal cord preparation. In these preparations (midbrain–pons lesioned animals), consciousness was thought to be lost even with elimination of the anaesthetic [8]. Furthermore, ketamine infusion was also stopped for 30 min to examine its effect on the segmental slow positive wave (P2 potential) (fig. 2) after transection of the most caudal part of the medulla (spinalized animals).

Two-way analysis of variance was conducted to identify significant differences in amplitude and latency changes in HSP and segmental spinal cord potentials after each surgical intervention. After this analysis, the least significant difference test for multiple comparison [9] was carried out when significant differences were found. With transection of the most caudal part of the medulla, the amplitudes of both HSP activated by heterosegmental stimulation diminished nearly to zero. For data analysis, these amplitudes were considered less than 1% of control and non-parametric Wilcoxon's signed ranks tests [10] were conducted to calculate statistical significance of differences from control values. $P < 0.05$ was considered significant.

Results

EXPERIMENT I: EFFECTS OF SPINAL CORD TRANSECTION

Neither HP–HSP nor FP–HSP changed significantly when the dorsal one-third of the cord was transected bilaterally at the T8–9 level (table 1, cuts 1 and 2). However, additional hemisection of the dorsal two-thirds of the contralateral cord decreased FP–HSP significantly (table 1, cut 3) with no concomitant significant change in HP–HSP. Bilateral transection of the dorsal two-thirds of the cord (table 1, cut 4) did not lead to further changes in HSP. With complete hemisection of the contralateral cord leaving the ventral one-third of the ipsilateral cord, both FP–HSP and HP–HSP were diminished significantly (table 1, cut 5). Complete transection of the cord caused both HP–HSP and FP–HSP to disappear (table 1, cut 6).

EXPERIMENT II: EFFECTS OF BRAIN RESECTION AND KETAMINE

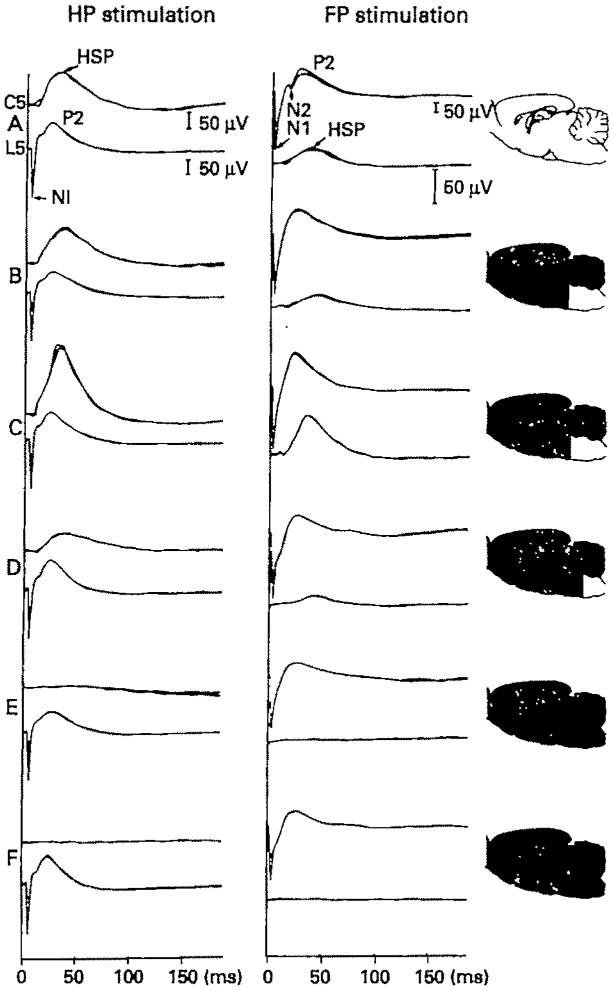

Figure 2 Examples of changes in HSP induced by lesions of the brain at various levels and by ketamine in medulla–spinal cord preparations. A: Before brain lesions during ketamine anaesthesia. HP = Hindpaw; FP = forepaw. Upper sweep, recorded at the C5 level; lower sweep, recorded at the L5 level. N1 = a slow (or sharp) negative wave of the segmental spinal cord potential (segSCP); P2 = a slow positive wave of segSCP; N2 = secondary slow negative wave of segSCP, also recordable in intact animals; HSP = heterosegmental slow positive spinal cord potential. B: HSP following destruction of the cerebral cortex, cerebellum, thalamus with hypothalamus, and midbrain with pons, at the level of AP ± 0, as shown in the right stereotactic drawing, according to Paxinos and Watson [7]. Note that there were no significant changes in HSP, but that the N2 of segSCP disappeared. C: HSP in this medulla–spinal cord preparation 30 min after cessation of ketamine infusion. HSP and P2 of the segSCP were markedly augmented. D: Effects of transecting the medulla oblongata at its middle level (AP -2.5 mm). Both HSP and P2 of segSCP were substantially decreased. E: Effects of transection at the most caudal part of the medulla oblongata at the level of AP -5.75 mm. Note that HSP disappeared and the P2 of segSCP decreased. F: Ketamine infusion was stopped for 30 min in this spinalized preparation. Note that HSP did not reappear, but that the P2 of segSCP was substantially augmented.

Resection of the cerebral cortex and whole cerebellum, and resection of the thalamus with the hypothalamus at the level caudal to the thalamus (Ap + 4.5 mm, see fig. 1) did not affect HSP significantly (table 2, lesions 1 and 2). Resection of the midbrain and pons at the level of AP ± 0 mm (fig. 1) did not decrease the amplitudes of HSP significantly (table 2, lesion 3). At this time, when continuous infusion of ketamine was stopped, HSP were increased significantly. Transection at the middle of the medulla oblongata (fig. 1) decreased HSP significantly (table 2, lesion 4). Transection of the medulla at the most caudal level (AP -5.75) (fig. 1) led to the disappearance of HSP (lesion 5). Even when ketamine infusion was stopped in this prep-

Table 1 Effects of spinal cord transection on HSP and segSCP evoked by hindpaw and forepaw stimulations in ketamine-anaesthetized rats. †Refer to figure 1 for cuts 1–6. aration, HSP did not reappear, but the segmental slow positive potential (P2) showed a significant increase in amplitude compared with that during infusion of ketamine.

Discussion

We have demonstrated that the ascending tract involved in the production of HSP was situated at the ventrolateral quadrant of the spinal cord, whereas the descending tract for the slow potentials was localized partially in the contralateral lateral funiculus and mostly in the bilateral ventrolateral quadrants.

The present study showed also that HSP were not changed significantly by lesions of the cerebral cortex, cerebellum, thalamus, midbrain and pons, but were diminished by transection of the middle part of the medulla and disappeared with transection of the most caudal part of the medulla. The results suggest that the feedback nuclei are situated diffusely in the medulla. Even in the midbrain–pons-eliminated preparation (the medulla–spinal cord preparation), termination of ketamine infusion augmented HSP, suggesting that ketamine produced a depressant effect on HSP also at the level of the central nuclei in the medulla oblongata. Transection of the most caudal part of the medulla led to the disappearance of HSP. Stopping infusion of ketamine in this spinal transection preparation again increased the amplitude of the slow positive component (P2) but not the negative (N1) component of the segmental spinal cord potential (segSCP), suggesting that ketamine also has a depressant effect on HSP and P2 at the level of the spinal cord.

The present method of spinal cord lesion was adopted after several other procedures, including radiofrequency cutting and injection of neurotoxins, were tested. Although these methods were simple, it was difficult to predict accurately the extent of the lesions. The present method of transecting the spinal cord was rather complicated, but may produce an accurately predictable lesion, which was supported by microscopic examination afterwards.

The resection and transection methods of the brain tissue under a microscope and stereotactic apparatus seemed more promising, as these provided an open field to observe the extent of lesion and the complete resection of the brain at a specific level. Blood transfusion was carried out in only three rats in which bleeding exceeded 20 ml kg^{-1} (25–30% of total blood volume). Arterial pressure and heart rate in the other animals were controlled easily by rapid transfusion of Ringer's lactate solution only. Thus this method of brain lesion seemed to be advantageous for defined destruction of brain tissue, provided that bleeding and blood transfusion were controlled properly.

Transection of the spinal cord at the thoracic level (T8–9) has been shown to produce lesions of the ascending tracts for HP–HSP and of the descending tracts for FP–HSP (fig. 1) [1–3, 6]. Bilateral transection of the dorsal one-third of the cord did not affect either FP–HSP or HP–HSP in the present study. This result indicates that the dorsal column system was not responsible for either ascending or descending tracts involved in the production of HSP. Bilateral transection of the dorsal two-thirds of the spinal cord which covers almost all of the dorsal and lateral columns did not affect HP–HSP, and contralateral hemisection of the ventrolateral quadrant and additional total transection decreased significantly and abolished HP–HSP, respectively. These results indicate that the ascending tracts which produce HP–HSP are located bilaterally in the ventrolateral spinal funiculi.

More than two sensory pathways have been shown to be involved in the ventrolateral quadrant; part of the spinothalamic tract projecting to the medial and intralaminar thalamus travelling through the ventromedial funiculus [11], and the spinoreticular system travelling within the ventrolateral quadrant [12–15], although some discrepancies have been reported also [16, 17].

As described in experiment II, HSP were not affected significantly by resection at the level between the thalamus and midbrain, indicating that the rostral part of the spinothalamic tract may not be responsible for the production of HSP. On the other hand, the caudal part of the spinoreticular system which travels through the ventrolateral quadrant [12–15] may be involved in these processes. Fur-

Table 2 Effects of brain lesions on HSP and segSCP evoked by hindpaw and forepaw stimulations in ketamine-anaesthetized and unanaesthetized rats. †Refer to figure 1 for lesions 1–5. HP–HSP = Heterosegmental spinal cord slow positive potential (HSP), recorded from the C5 level, in response to hindpaw (HP) stimulation; HP–segSCP N1 and P2 = slow negative (N1) and positive (P2) waves of the segmental spinal cord potential (segSCP), recorded from the L5 level, in response to HP stimulation; FP–HSP = HSP, recorded from the L5 level, in response to forepaw (FP) stimulation; FP–segSCP N1 and P2 = slow negative (N1) and positive (P2) waves, recorded from the C5 level, in response to forepaw stimulation. Values are mean (SD) calculated in 14 rats. U = unanaesthetized state (30 min after stopping the infusion of ketamine). $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$, compared with control. ‡$P < 0.05$, ‡‡$P < 0.01$ compared with value during ketamine anaesthesia

thermore, the partial decrease in response to lesion of the contralateral ventrolateral quadrant, and complete disappearance of HSP by total transection of the cord indicated that the ascending pathways involved in the production of these slow potentials are partly crossed and partly uncrossed in the ventrolateral quadrant.

Contralateral section of the dorsal two-thirds of the cord decreased significantly FP–HSP, indicating that descending fibres are located partially in this portion. Ipsilateral dorsolateral funiculi may not contain the descending fibres for FP–HSP, as additional section of this portion did not induce further changes in FP–HSP (table 1).

Contralateral hemisection of the ventrolateral cord profoundly affected FP–HSP and total transection of the cord completely eliminated the appearance of FP–HSP. This result indicates that the descending fibres required for production of FP–HSP are situated predominantly in the ventral quadrant of the cord.

Several studies have shown that both the raphe spinal and nucleus reticularis paragigantocellularis (or nucleus reticularis gigantocellularis) spinal tracts travel through bilateral dorsolateral funiculi [18–23]. These tracts have been thought to be important systems for descending inhibitory control of fast pain transmission at the spinal level. In the present study, however, these systems appeared to be involved only partially in the production of HSP, as HSP occurred even with destruction of these two nuclei, and transection of the dorsal one-third of the cord, which includes part of the dorsolateral column, did not affect HSP significantly.

It has been shown also that the pontine and medullary reticulospinal tracts are located in the ventral, ventrolateral and the most ventral portions of the dorsolateral funiculus [24]. Similarly, the rostral part of the medullary raphe nuclei such as the nucleus raphe magnus descends mainly through the dorsolateral funiculus, while the fibres from the caudal parts of the raphe nuclei such as the nuclei raphe pallidus and obscurus are located mainly in the ventral and ventrolateral funiculi [25–27]. Therefore, one or more of these structures could be the candidate which feeds back the impulses to form the descending tract for HSP.

Our data indicate that no brain structures rostral to the medulla (the entire cerebral cortex, thalamus, midbrain, pons and cerebellum) are responsible for producing HSP in ketamine-anaesthetized rats. This does not imply that the central nervous system rostral to the medulla oblongata does not influence HSP. There are four possible explanations for the lack of significant changes in HSP after lesions at or rostral to the pons: (i) ketamine might have substantially suppressed the influences from the higher central nervous system (CNS), resulting in insignificant changes in response to the lesions; (ii) some functional compensation may occur in the CNS, and the lower CNS could take over the function of the higher CNS during the 30-min wait for recovery from traumatic neuronal shock; (iii) the CNS rostral to the medulla may make no contribution to the production of HSP; and (iv) these higher CNS structures may have supplementary influences (facilitatory and inhibitory) on HSP production, whereas the medulla oblongata may be the principal site for feeding back the impulses to the spinal cord to produce HSP.

The fourth mechanism might be the more relevant in view of the results of our present and previous studies [1–5]. In the present study, HSP were augmented markedly by discontinuing the ketamine infusion. This finding supports data from our previous studies that the latencies of HSP are variable in intact rats even during ketamine anaesthesia [2] and divided into two groups in conscious human subjects [5]. Previous studies in cats [26–31] demonstrated that primary afferent depolarization (PAD) could be evoked by stimulation of several CNS structures. These findings support the fourth mechanism proposed above that the principal nuclei involved in HSP production might be situated in the medulla but be influenced by other higher CNS structures.

The substantial decrease in HSP amplitudes observed in middle medulla-lesioned preparations indicates that part of the site responsible for impulse feedback may be situated at or rostral to the middle medulla. Although we could not define a specific nucleus within the medulla oblongata by the present method, it is probable that at least some of the feedback neurones are also located at a rostral region within the medulla.

Additional lesions at the level of the most caudal part of the medulla oblongata abolished HSP completely (table 2). This indicates that another nucleus may be situated within the caudal part of the medulla, and that this part is the site most responsible for the feedback of impulses producing HSP. The caudal part of the medulla does not contain the raphe magnus but includes medullary reticular formations. These structures are known to be tonically influenced by the midbrain reticular formation or periaqueductal grey matter [16, 17, 24–27]. Thus from our present results and those of previous reports on descending inhibitory control of spinal sensory transmission including pain, it is probable that HSP reflect the activities of descending controls activated by heterotopic sensory stimulation.

Recently, it was reported that diffuse noxious inhibitory control (DNIC) was not affected by destruction of PAG, cuneiformis nucleus and parabrachial nucleus by injection of ibotenic acid in the rat, suggesting that the nuclei responsible for DNIC are situated in the caudal part of the medulla. As shown in our previous report [2], however, the neuronal mechanisms may be different between DNIC and HSP, as DNIC is produced only by noxious stimulation [6, 32] while HSP are produced by both non-noxious and noxious stimuli [2–5]. Therefore, we could not document if there is any similarity in the central nuclei producing DNIC and those responsible for the HSP.

Ketamine has been shown to affect cortical and thalamic neuronal activities [33], while having little effect on the midbrain reticular formation [34]. Nevertheless, cessation of ketamine infusion greatly augmented HSP even in the midbrain and pons-lesioned preparations which still contained the medullary reticular formation. Furthermore, slow positive waves (P2) in the segmental spinal cord potential were affected by ketamine in the medulla-lesioned animals (spinalized preparation) (table 2), as observed previously in intact human [35] and rabbit spinal cords [36].

There have been no reports on the effects of ketamine on the activity of the medulla oblongata derived from the influence of higher central nervous structures. The present results have shown that ketamine exhibits depressant effects on FP–HSP and HP–HSP in medulla–spinal cord preparations, and even a slight but significantly depressant effect on the slow P wave (P2) of the segSCP in spinalized preparations, while the negative wave (N1) of the segSCP remained unchanged. The results of the present study indicate that the depressant effects of ketamine on these feedback potentials (FP–HSP and HP–HSP) originated at least in part from the medulla in which the principal nuclei of the HSP are suggested to be localized. The present findings indicate also that segmental PAD, reflected as the P2 of the segmental SCP [1–5], was also suppressed by ketamine in agreement with the results of our previous study in the intact human spinal cord [35]. From this effect of ketamine on the P2 of the segmental SCP, it is also conceivable that the depressant effect of the drug on both FP–HSP and HP–HSP is also in part exerted at the spinal segment level.

Indeed, nociceptive responses [37] and wind-up [38] of dorsal horn neurones have been found to be suppressed by intrathecal pretreatment with the NMDA receptor antagonists, MK-801 [38] and ketamine [39]. On the other hand, our own laboratory [40] has also shown that NMDA antagonists, MK-801 and ketamine, have somewhat different depressant actions depending on NMDA receptor subtypes. Therefore, inhibitory effects of ketamine on the dorsal horn may not be the same in all types of neurones which contribute to production of HSP.

Our previous studies [2–5] have suggested that these slow heterosegmental slow positive potentials, FP–HSP and HP–HSP, reflect the feedback inhibitory potentials, presumably PAD, although more studies should be carried out to establish the relationship between HSP and feedback PAD, and also between rat HSP and human HSP [5]. Thus depressant effects of the drug on these inhibitory potentials may lead to relative excitement in terms of sensory transmission within the cord. Preservation of reflexes and involuntary movements frequently observed during ketamine anaesthesia might be a result at least in part of the depressant effect of the drug on these feedback inhibitory potentials and its segmental inhibitory mechanism.

Relaxant effect of ketamine and its isomers on histamine-induced contraction of tracheal smooth muscle

K. HIROTA, T. SATO, S. F. RABITO, E. K. ZSIGMOND AND A. MATSUKI

Summary

The mechanism by which racemic ($R(\pm)$) ketamine relaxes airway smooth muscle is unclear and there is no information on the differential effects of ketamine and its isomers. In this study, we have examined the spasmolytic effect of $R(\pm)$ ketamine and its isomers $S(+)$ and $R(-)$ ketamine and the role of intracellular calcium and opioid receptors in $R(\pm)$ ketamine-induced relaxation. The tension of isolated guinea pig tracheal strips was measured isometrically with a force displacement transducer and contraction elicited with histamine 10^{-5} mol litre^{-1}. In histamine-preconstricted strips, the two ketamine isomers (4.5–18.0 × 10^{-4} mol litre^{-1}) produced equipotent relaxation. A subthreshold dose of each isomer of ketamine (10^{-4} mol litre^{-1}) which alone did not relax histamine-induced contraction ($S(+)$, $P < 0.01$; $R(\pm)$, $P < 0.01$; $R(-)$, $P < 0.05$) significantly potentiated adrenaline 1.25–5.0 × 10^{-9} mol litre^{-1}-induced relaxation (potency: $S(+) > R(\pm) > R(-)$). Increase in extracellular Ca^{2+} (1.8–14.4 × 10^{-3} mol litre^{-1}) significantly reduced $R(\pm)$ ketamine-induced relaxation. $S(-)$ Bay K 8644, at concentrations up to 2.0 × 10^{-6} mol litre^{-1}, partially antagonized $R(\pm)$ ketamine-induced relaxation whereas at 10^{-5} mol litre^{-1} or higher it potentiated the response. Naloxone 1.5–6.0 × 10^{-6} mol litre^{-1} did not affect the relaxation caused by $R(\pm)$ ketamine. We conclude that although both ketamine isomers produced equipotent spasmolytic effects on airway smooth muscle precontracted with histamine, they differed in their ability to potentiate the relaxing effect of adrenaline. $S(+)$ ketamine produced the greatest potentiation. Changes in intracellular Ca^{2+} level secondary to a reduction in the L-type Ca^{2+} current may partially mediate the spasmolytic effect of $R(\pm)$ ketamine. (*Br. J. Anaesth.* 1996; **76**: 266–270)

Key words

Anaesthetics i.v., ketamine. Pharmacokinetics, stereoisomers. Airway, muscles. Histamine.

Racemic ($R(\pm)$) ketamine is a potent bronchodilator and has been used for the anaesthetic management of asthmatic patients [1–4]. Although previous reports suggested that the bronchodilator action of $R(\pm)$ ketamine may be caused by increased catecholamine concentrations [5], or by β receptor activation [6], Ca^{2+} channel block [7–9], or both, the precise mechanism of action remains to be determined.

There are many pharmacological differences between optical isomers of ketamine [10–13]. Lundy and colleagues [12] reported that $S(+)$ ketamine can potentiate responses to catecholamines in vascular and anococcygeus muscles to a greater extent than $R(-)$ ketamine. However, the differential effects of ketamine isomers on the response of airway smooth muscle to adrenaline have not yet been reported.

In this study we have determined if ketamine isomers have differential spasmolytic effects on tracheal strips precontracted with histamine and differential potentiating effects on the relaxation produced by adrenaline. In addition, we have studied the role of increased extracellular calcium and opioid receptors on these responses.

Materials and methods

The study was approved by the Animal Care and Use Committee of the University of Illinois at Chicago.

GUINEA PIG TRACHEAL STRIP

Female guinea pigs (300–450 g) were killed with an overdose of sodium pentobarbitone 75 mg kg^{-1} i.p. and section of the abdominal aorta. The trachea was removed, dissected from surrounding tissue and then cut spirally into strips (3 mm × 15 mm) which were mounted in a 10-ml organ bath filled with oxygenated (95% oxygen–5% carbon dioxide) Tyrode's solution at 37 °C. The composition of Tyrode's solution was (mmol litre^{-1}): NaCl 138, KCl 2.7, $MgCl_2$ 1.05, $NaHPO_2$ 0.42, $NaHCO_3$ 11.9, glucose 5.5 and $CaCl_2$ 1.8. Each strip was attached between a fixed point and a force displacement

transducer (FT03, Grass Instrument Co., Quincy, MA, USA). After obtaining reproducible contractions to histamine 10^{-5} mol litre^{-1}, experiments were begun. $R(\pm)$, $S(+)$ and $R(-)$ ketamine were tested in random order. Strips were washed for 10 min before each contraction was induced by histamine.

The first experiment was designed to determine the effect of ketamine and its isomers on the tone of tracheal strips precontracted with histamine ($n = 6$). After eliciting maximal contraction to histamine, $R(\pm)$, $S(+)$ or $R(-)$ ketamine was cumulatively added to the organ bath (0.45–1.8 × 10^{-3} mol litre^{-1}). Relaxation was expressed as a percentage (peak contraction, 0 %, fully relaxation, 100 %). The ED_{50} of ketamine (the dose of ketamine that reversed histamine-induced contraction by 50 %) was calculated from the ketamine dose–response curves.

In the second study, we examined the effect of a subthreshold dose of $R(\pm)$ ketamine and its isomers on relaxation induced by adrenaline ($n = 6$). The subthreshold dose of $R(\pm)$ ketamine and its isomers, which alone did not produce relaxation, was determined from the first study. After maximal contraction of each strip was elicited with histamine, 0.9 % saline or $R(\pm)$, $S(+)$ or $R(-)$ ketamine 10^{-4} mol litre^{-1} was administered into the organ bath. Five minutes later, adrenaline was given cumulatively (1.25–5.0 × 10^{-9} mol litre^{-1}) to obtain a dose–response curve to calculate its ED_{50}.

In the third study, we tested if increases in extracellular Ca^{2+} concentration by addition of $CaCl_2$ modified the relaxation produced by $R(\pm)$ ketamine ($n = 6$). The relaxation produced by $R(\pm)$ ketamine 1.8 × 10^{-3} mol litre^{-1} was measured when Ca^{2+} concentrations in the perfusate were increased from 1.8 to 14.4 × 10^{-3} mol litre^{-1}.

In the fourth study ($n = 8$), we tested if the L-type Ca^{2+} channel opener $S(-)$ Bay K 8644 reversed the spasmolytic effect of $R(\pm)$ ketamine. When reproducible contractions to histamine were established, $R(\pm)$ ketamine 9.0 × 10^{-4} mol litre^{-1} was added to the bath followed by cumulative administration of $S(-)$ Bay K 8644 from 2 × 10^{-7} to 10^{-5} mol litre^{-1}.

In the fifth study ($n = 6$), we examined the effect of naloxone on $R(\pm)$ ketamine-induced relaxation. Tracheal strips were precontracted with histamine and the relaxation produced by $R(\pm)$ ketamine 9.0 × 10^{-4} mol litre^{-1} was studied alone and in the presence of naloxone 1.5 × 10^{-6} mol litre^{-1}

DATA ANALYSIS

All data are expressed as mean (SEM). Statistical analysis was by one-way and repeated measures ANOVA followed by Scheffé's *F* test. $P < 0.05$ was considered significant.

DRUGS AND SOLUTIONS

$R(\pm)$ ketamine hydrochloride and histamine hydrochloride were obtained from Sigma Chemical Co. (St Louis, MO, USA), sodium pentobarbitone from Abbott Laboratories (North Chicago, IL, USA) and naloxone from DuPont Pharmaceuticals (Manati, Puerto Rico). $S(+)$, $R(-)$ ketamine hydrochloride was generously donated by Parke-Davis GmbH (Munich, Germany). $S(-)$ Bay K 8644 was obtained from Research Biochemicals Inc. (Natick, MA, USA).

Stock solutions of naloxone and ketamine were prepared in distilled water; $S(-)$ Bay K 8644 was dissolved in methanol (2.8 × 10^{-3} mol litre^{-1}). All stock solutions were stored as aliquots at −20 °C.

Results

EFFECT OF KETAMINE AND ITS ISOMERS ON HISTAMINE-INDUCED CONTRACTIONS

Histamine 10^{-5} mol litre^{-1} increased basal tension by 1.33 (SEM 0.29) g ($n = 6$). After precontraction with histamine, $R(\pm)$ ketamine and its isomers relaxed the tracheal strips in a concentration-dependent manner (fig. 1). There were no significant differences

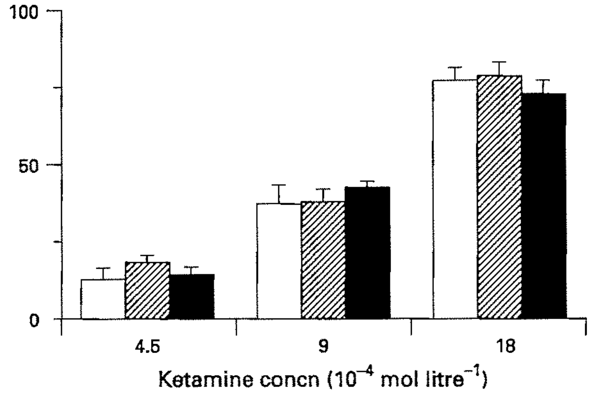

Figure 1 Spasmolytic effect of $R(\pm)$ (▨), $S(+)$ (■) and $R(-)$ (□) ketamine on histamine-induced guinea pig tracheal contractions ($n = 6$). There were no significant differences in the spasmolytic effect between the three forms of ketamine. All values are mean, SEM.

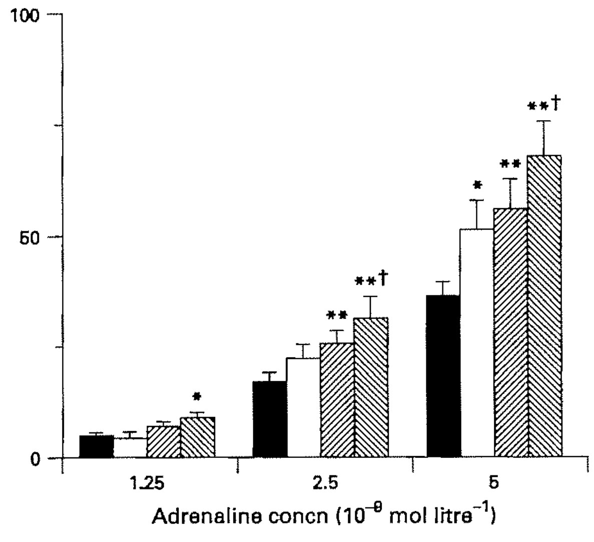

Figure 2 Differential effect of a subthreshold dose (10^{-4} mol litre^{-1}) of each of $R(\pm)$ (▨), $S(+)$ (▧) and $R(-)$ (□) ketamine which potentiated the relaxation of tracheal strips produced by adrenaline. All tracheal strips ($n = 6$) were precontracted with histamine 10^{-5} mol litre^{-1}. $^*P < 0.05$, $^{**}P < 0.01$ compared with adrenaline alone (■); $^\dagger P < 0.05$ compared with adrenaline and $R(-)$ ketamine.

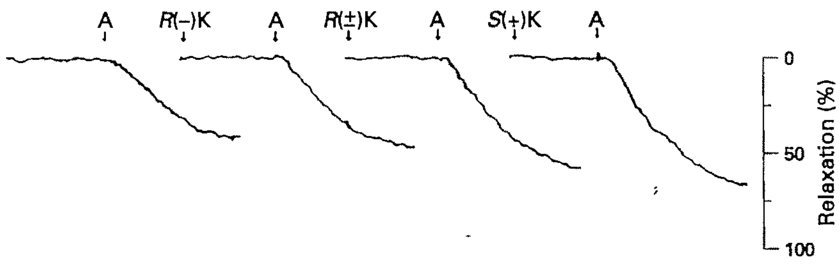

Figure 3 Original recording showing the differential potentiation of a subthreshold dose (10^{-4} mol litre^{-1}) of $R(\pm)$, $S(+)$ and $R(-)$ ketamine (K) on adrenaline (A) 5.0×10^{-9} mol litre^{-1}-induced tracheal relaxation. Each ketamine isomer was given 5 min before the administration of adrenaline. The tracheal strips were precontracted with histamine 10^{-5} min litre^{-1}.

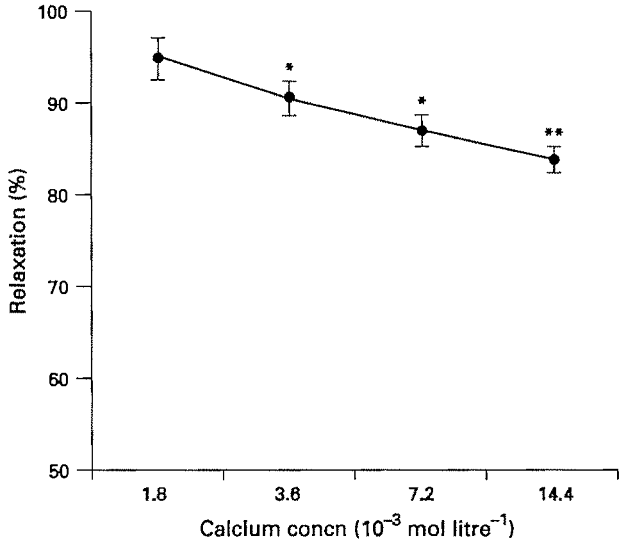

Figure 4 Effect of increasing the extracellular calcium concentration on the relaxation of tracheal strips ($n = 6$) produced by $R(\pm)$ ketamine 1.8×10^{-3} mol litre^{-1}. All tracheal strips were precontracted with histamine 10^{-5} mol litre^{-1}. All values are mean, SEM. $^{*}P < 0.05$, $^{**}P < 0.01$ compared with standard calcium concentration (1.8×10^{-3} mol litre^{-1}) in Tyrode's solution.

between the ED_{50} values of $R(-)$, $R(\pm)$ and $S(+)$ ketamine: 1.14 (0.11), 1.13 (0.09) and 1.09 (0.05) $\times 10^{-3}$ mol litre^{-1}, respectively ($n = 6$). This relaxant effect of $R(\pm)$ ketamine and its isomers was fully reversible after washout.

EFFECT OF A SUBTHRESHOLD DOSE OF KETAMINE AND ITS ISOMERS ON ADRENALINE-INDUCED RELAXATION

Adrenaline relaxed histamine precontracted tracheal strips ($n = 6$) in a concentration-dependent manner (fig. 2). A subthreshold dose (10^{-4} mol litre^{-1}) of $R(-)$, $R(\pm)$ and $S(+)$ ketamine did not change the tension of strips precontracted with histamine (fig. 3). However, the same subthreshold dose significantly reduced the ED_{50} value of adrenaline from 9.4 (1.4) to 5.7 (0.9) $\times 10^{-9}$ mol litre^{-1} after $R(-)$ ketamine ($P < 0.05$); to 4.9 (0.8) $\times 10^{-9}$ mol litre^{-1} after $R(\pm)$ ketamine and to 4.0 (0.8) $\times 10^{-9}$ mol litre^{-1} after $S(+)$ ketamine ($P < 0.01$). $S(+)$ ketamine was more potent than $R(-)$ ketamine at adrenaline 2.5 and 5.0×10^{-9} mol litre^{-1} ($P < 0.05$, fig. 2). The relaxant effect of adrenaline was also fully reversible after washout.

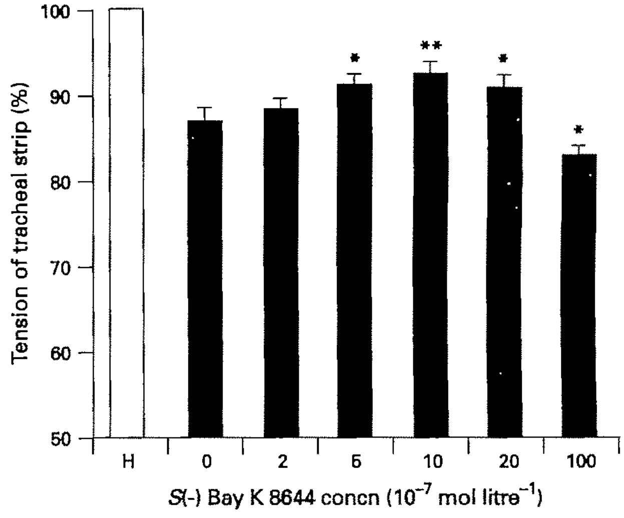

Figure 5 Effect of $S(-)$ Bay K 8644, an L-type calcium channel activator, on the relaxation of tracheal strips ($n = 8$) produced by $R(\pm)$ ketamine 9×10^{-4} mol litre^{-1}. All tracheal strips were precontracted with histamine 10^{-5} mol litre^{-1}. All values are mean, SEM. $^{*}P < 0.05$, $^{**}P < 0.01$ compared with $R(\pm)$ ketamine alone.

EFFECT OF Ca^{2+} CONCENTRATION ON KETAMINE-INDUCED RELAXATION

$R(\pm)$ ketamine 1.8×10^{-3} mol litre^{-1} caused 89.7 (4.6)% relaxation of histamine-induced strip contractions. Increasing the extracellular Ca^{2+} concentration from 1.8 to 14.4×10^{-3} mol litre^{-1} reduced $R(\pm)$ ketamine relaxation by 22.2% (fig. 4, $n = 6$).

EFFECT OF $S(-)$ BAY K 8644, AN L-TYPE Ca^{2+} CHANNEL OPENER, ON KETAMINE-INDUCED RELAXATION

$S(-)$ Bay K 8644 decreased the relaxation of the strips ($n = 8$) produced by $R(\pm)$ ketamine. The maximal effect occurred with $S(-)$ Bay K 8644 10^{-6} mol litre^{-1}. However, $S(-)$ Bay K 8644 10^{-5} mol litre^{-1} potentiated $R(\pm)$ ketamine-induced relaxation (fig. 5).

EFFECT OF NALOXONE ON KETAMINE-INDUCED RELAXATION

$R(\pm)$ ketamine 9.0×10^{-4} mol litre^{-1} significantly reduced histamine-induced contractions from 100 to 64.5 (4.4)% ($n = 6$, $P < 0.01$). However, naloxone added cumulatively (1.5, 3.0 and 6.0×10^{-6} mol litre^{-1} in the bath) did not significantly change relaxation from 64.5 (4.4)% to 64.9 (4.6)%, 67.8 (4.6)% and 62.0 (4.2)%, respectively.

Discussion

$R(\pm)$ ketamine is known to produce bronchodilatation in asthmatic patients who do not respond to conventional therapy [1–4]. Although the mechanism of this spasmolytic effect of $R(\pm)$ ketamine is still unclear, previous studies suggested that Ca^{2+} channel blocking effects [7–9], catecholamine release [5] and/or inhibition of catecholamine uptake [12, 13] may contribute. In addition, Fink and Ngai [11] reported that $R(\pm)$ ketamine inhibited the contractile response of the ileum to electrical stimulation and they suggested that this inhibition by $R(\pm)$ ketamine was mediated partially via opioid receptors.

In the present study, when extracellular Ca^{2+} was increased, the relaxing action of $R(\pm)$ ketamine was reduced in a concentration-dependent manner. Moreover, the L-type Ca^{2+} channel opener, $S(-)$ Bay K 8644, but not naloxone, partially antagonized the relaxation induced by $R(\pm)$ ketamine. Therefore, the spasmolytic effect of $R(\pm)$ ketamine may be caused partially by reduction in L-type Ca^{2+} channel activity. $R(\pm)$ ketamine may produce its relaxant action on airway smooth muscle by inhibition of agonist-induced second messenger synthesis such as inositol 1,4,5-triphosphate [14] or by stimulating Ca^{2+} ATPase to cause Ca^{2+} efflux [15], or both. Further investigation of the action of ketamine at the subcellular level is needed to clearly identify the mechanisms of action, as other modulators such as diacylglycerol, protein kinase C or G proteins may be involved in the relaxing effect of ketamine. We found that $S(-)$ Bay K 8644 10^{-5} mol litre^{-1} potentiated the relaxation produced by $R(\pm)$ ketamine although up to 10^{-6} mol litre^{-1} antagonized the relaxation in a concentration dependent manner. As we dissolved $S(-)$ Bay K 8644 in methanol (0.36% $S(-)$ Bay K 8644 10^{-5} mol litre^{-1}), this may potentiate the effect of ketamine. However, this finding is consistent with previous reports [16–19] that this Ca^{2+} channel opener has a biphasic effect on vascular smooth muscle and cardiac muscle. Wei and colleagues demonstrated that the dual effects of $S(-)$ Bay K 8644 were not caused by involvement of the antagonists isomer, $R(-)$ Bay K 8644 [17]. Another study showed that $S(-)$ Bay K 8644 potentiated or inhibited Ca^{2+} current at polarized and depolarized potentials, respectively [18].

Although the pharmacological differences [10–13] between the ketamine isomers, $S(+)$ and $R(-)$ ketamine, are known, their differential spasmolytic effects on contracted airways have not been reported. Our previous report [9] showed that both isomers equipotently inhibited contraction of guinea pig ileum induced by inflammatory mediators, whereas Fink and Ngai [11] demonstrated that $S(+)$ ketamine was 2–3 times more potent than $R(-)$ ketamine in relaxing guinea pig ileum precontracted by electrical stimulation. In the present study we found that ketamine isomers produced equipotent spasmolytic effects on tracheal strips precontracted with histamine, a result consistent with our previous study on guinea pig ileum [9].

Using rabbit vascular smooth muscle and rat anococcygeus muscle, Lundy, Gverzdys and Frew [20] found that $R(\pm)$ ketamine potentiated the catecholamine response by inhibition of extraneuronal uptake. Using the same muscles [12] they also demonstrated that $S(+)$ ketamine inhibited catecholamine uptake more than $R(-)$ ketamine. In the present study, we found similar results as the subthreshold dose of $R(\pm)$ ketamine and its isomers potentiated adrenalinè-induced relaxation of tracheal strips precontracted by histamine and the potentiating effect of $S(+)$ ketamine was greater than that of $R(-)$ ketamine.

We conclude that the spasmolytic effect of $R(\pm)$ ketamine on contracted airway smooth muscle may result partially from a decrease in Ca^{2+} influx through the L-type Ca^{2+} channel and from inhibition of catecholamine uptake. We suggest that ketamine (especially $S(+)$ ketamine) could be a useful therapeutic agent, in combination with a β_2 agonist, for the treatment of status asthmaticus.

Interaction of i.v. anaesthetic agents with 5-HT_3 receptors

B. L. APPADU AND D. G. LAMBERT

Summary

Using N1E-115 neuroblastoma cells as an experimental model, we have examined if four commonly used i.v. anaesthetic induction agents interact with 5-HT_3 receptors. Specifically, we tested the hypothesis that the antiemetic effects of propofol may result from 5-HT_3 receptor antagonism. Binding of tropisetron (a 5-HT_3 selective reference compound), etomidate, ketamine, thiopentone and propofol to 5-HT_3 receptors was assessed by measuring the displacement of [^{3}H]BRL 43694 from whole N1E-115 cells. The rank order potency (K_i) was tropisetron (1.7 (SEM 0.2) nmol litre^{-1}) $\geqslant$ etomidate (83 (4) µmol litre^{-1}) $\geqslant$ ketamine (97 (4) µmol litre^{-1}) > thiopentone (177 (9) µmol litre^{-1}) > propofol (819 (171) µmol litre^{-1}). With the exception of thiopentone these effects were outside the clinical range and suggest that anaesthetic agents are unlikely to interact directly with 5-HT_3 receptors, and that other mechanism(s) must underlie the antiemetic effects of propofol. (*Br. J. Anaesth.* 1995; **76**: 271–273)

Key words

Anaesthetics i.v. Vomiting, nausea. Vomiting, antiemetics. Serotonin (5-hydroxytryptamine). Model, neuroblastoma cells.

Nausea and vomiting are distressing side effects of general anaesthesia. The pathogenesis of postoperative nausea and vomiting is multifactorial [1]. It has been shown that the 5-HT_3 receptor, a member of the ligand-gated, ion channel family [2], is densely located in areas known to be involved in the emetic reflex and could be the key receptor involved in nausea and vomiting [3]. The importance of the 5-HT_3 receptor has been demonstrated in clinical practice where 5-HT_3 antagonists have been used to suppress nausea and vomiting caused by emetic agents [4, 5]. Indeed, selective 5-HT_3 receptor antagonists appear to prevent acute emesis by blocking the initiation of the emetic reflex produced via 5-hydroxytryptamine (5-HT) release from enterochromaffin cells in the gastrointestinal tract in addition to blocking 5-HT_3 receptors in the brain [6].

General anaesthesia with propofol is associated with a decreased incidence of early postoperative nausea and vomiting [7–9]. However, it is unlikely that propofol exerts its antiemetic action via sedation as the duration of its antiemetic effect outlasts its hypnotic effect. It has been suggested recently that propofol has significant direct antiemetic properties [10]. While the exact mechanism of the antiemetic action of propofol is unknown we have recently shown that these effects are unlikely to result from dopamine D_2 receptor antagonism [11]. Using the murine neuroblastoma cell line, N1E-115, as a 5-HT_3 expression system [12], we have examined the effects of four commonly used i.v. anaesthetic induction agents on the binding of [^{3}H]BRL 43694 to 5-HT_3 receptors.

Materials and methods

Mouse neuroblastoma cells of the clone N1E-115 were cultured in Dulbecco's modified Eagle's medium. The growth medium was supplemented with 10% fetal calf serum, with the antibiotics penicillin 100 u. ml^{-1}, streptomycin 100 µg ml^{-1} and Fungizone 2.5 µg ml^{-1}. Cells were cultured to subconfluence in a humidified atmosphere containing 5% carbon dioxide at 37 °C and were passaged every 5–7 days with re-feeding every third day.

Drugs used included: propofol (Zeneca Pharmaceuticals, Macclesfield, UK, lot: 71013/91A) solubilized in dimethylsulphoxide (DMSO); etomidate hydrochloride (Janssen Pharmaceuticals, Bucks, UK); sodium thiopentone (Rhone-Poulenc Rorer, Dagenham, UK, batch 62800) solubilized at 1 mmol litre^{-1} in NaOH 1.0 mol litre^{-1} (when this was added to the binding assay buffer, > 100 × dilution, the pH remained unchanged at 7.4); ketamine hydrochloride (Sigma, Dorset, UK), ICS 205-930 (3-tropanyl-indole-3-carboxylate hydrochloride, tropisetron, Semat, St Albans, UK), [^{3}H]BRL 43694 (specific activity 85.5 Ci mmol^{-1}, NEN Research Products, Herts, UK).

BINDING STUDIES

Binding of i.v. anaesthetic agents to 5-HT_3 receptors was studied using displacement of a fixed concentration (approximately 0.4 nmol litre^{-1}) of the high affinity 5-HT_3 selective antagonist, [^{3}H]BRL

B. L. APPADU, MD, FRCA, D. G. LAMBERT, BSC (HONS), PHD, University Department of Anaesthesia, Leicester Royal Infirmary, Infirmary Close, Leicester LE1 5WW. Accepted for publication: September 6, 1995.

Correspondence to B.L.A.

43694. After removal of growth medium, cells were harvested, washed three times, and resuspended in Krebs–HEPES buffer, pH 7.4, of the following composition (mmol litre^{-1}): Na^+ 143.3, K^+ 4.7, Ca^{2+} 2.5, Mg^{2+} 1.2, Cl^- 125.6, $H_2PO_4^{2-}$ 1.2, SO_4^{2-} 1.2, glucose 11.7 and HEPES 10. Cells were incubated at 37 °C for 60 min in 1-ml volumes of Krebs–HEPES buffer, in the presence of [^{3}H]BRL 43694 and increasing concentrations of displacing drugs (i.v. anaesthetic agents and tropisetron). Bound and free ligand were separated by vacuum filtration onto Whatman GF/B filters using a Brandel cell harvester. Radioactivity retained on the filters was measured by liquid scintillation spectrophotometry. Non-specific binding was defined in the presence of excess tropisetron (10 μmol litre^{-1}) and amounted to $4.8 \pm 1.6\%$ ($n = 34$).

DATA ANALYSIS

The concentration of displacer producing 50% displacement (IC_{50}) was estimated by computer-assisted curve fitting (Graphpad-Prism). IC_{50} values were corrected for the competing mass of [^{3}H]BRL 43694 according to Cheng and Prusoff [13] using a K_D (equilibrium dissociation constant) value for [^{3}H]BRL 43694 of 0.3 nmol litre^{-1} [14] to yield K_i. Statistical comparison of K_i values was made using Student's unpaired t test and considered significant when $P < 0.05$.

Results

Binding of [^{3}H]BRL 43694 was displaced in a dose dependent manner by the $5HT_3$ selective reference compound, tropisetron. The calculated affinity (1.7 nmol litre) was consistent with previous reports [15–17]. In addition, there was a dose-dependent displacement of [^{3}H]BRL 43694 by the four anaesthetic agents tested. The curves shown in figure 1 and analysed in table 1 are based on maximum displacement of 100%, although this was not achieved experimentally. The rank order potency was etomidate ≥ ketamine > thiopentone > propofol. DMSO, the vehicle for propofol, produced < 5% displacement of [^{3}H]BRL 43694 at the highest concentration (300 μmol litre^{-1}) of propofol only. With the exception of thiopentone, these effects fell outside the clinically relevant serum concentrations [18–21].

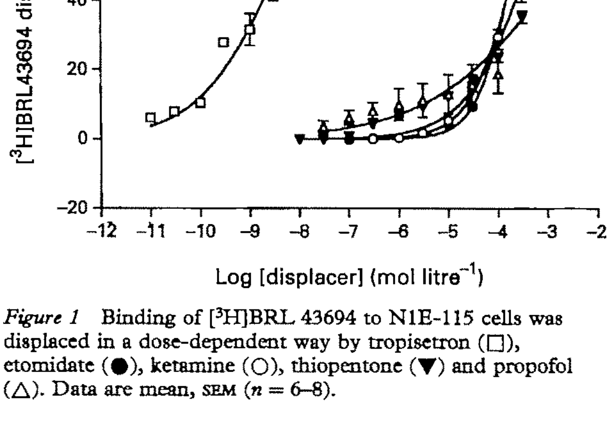

Figure 1 Binding of [^{3}H]BRL 43694 to N1E-115 cells was displaced in a dose-dependent way by tropisetron (□), etomidate (●), ketamine (○), thiopentone (▼) and propofol (△). Data are mean, SEM (n = 6–8).

Table 1 K_i values (mean (SEM)) for tropisetron and the four i.v. anaesthetic agents. Data are derived from the curves in figure 1. ‡ Peak at induction, not corrected for protein binding. Subhypnotic doses would be lower. * $P < 0.05$, less potent than ketamine and etomidate; † $P < 0.05$, less potent than thiopentone, ketamine and etomidate

	n	K_i	Clinical concn‡ (μmol litre^{-1})
Tropisetron	6	1.7 (0.2) nmol litre^{-1}	Not available
Etomidate	6	83.2 (3.8) μmol litre^{-1}	10 [18]
Ketamine	6	96.9 (3.5) μmol litre^{-1}	20 [19]
Thiopentone	6	177.3 (9.4) μmol litre^{-1}*	380 [20]
Propofol	8	819.0 (171.3) μmol litre^{-1}†	35 [21]

Discussion

We have demonstrated that four commonly used i.v. anaesthetic induction agents exert little direct effect on endogenous 5-HT_3 receptors in a cultured neuronal cell line, N1E-115. There was some overlap with the K_i for thiopentone and the observed peak serum concentration. However, these studies do not enable predictions to be made as to whether thiopentone is acting as an agonist (emetic) or antagonist (antiemetic). More importantly, our studies suggested that the reported antiemetic action of propofol [7–9] is unlikely to be caused by 5-HT_3 receptor block as the K_i values of propofol exceeded the peak plasma and brain [22] anaesthetic concentrations. In addition, the K_i was approximately 25-fold greater than plasma propofol concentrations at subhypnotic doses, where a significant antiemetic action can be demonstrated [7–9]. However, it should be noted that there may be interspecies variation in the 5-HT_3 receptor and consequently K_i values in mouse cells may not be a true reflection of those in humans.

Our results are at variance with the findings of a recent study of the action of i.v. anaesthetics with the 5-HT_3 receptor by Barann and colleagues [23], who found that i.v. anaesthetics inhibited 5-HT-induced flux of ^{14}C-guanidinium through the cation channel of the 5-HT_3 receptor. The rank order of potency in their study was propofol > etomidate > thiopentone > ketamine (in our study we found propofol the least potent). This functional block of the 5-HT_3 receptor by anaesthetic drugs may result from channel block rather than receptor antagonism, but suggests that direct 5-HT_3 receptor antagonism may not be *the only way* to reduce emesis, in that "downstream" functional block may also be important. As the inhibition of ^{14}C-guanidinium influx [23] was non-competitive, this modifies the general conclusions of our study. While there does not appear to be 5-HT$_3$ receptor block, channel inhibition by anaesthetic agents appears to be a viable and potent [23] mechanism for producing antiemesis. However, thiopentone and etomidate do not appear to exert significant antiemetic action but still reduce 5-HT$_3$ function at clinically relevant doses.

Effects of morphine on human nasal cilia beat frequency *in vitro*†

D. A. SELWYN, J. H. RAPHAEL, D. G. LAMBERT AND J. A. LANGTON

Summary

Using human nasal cytological brushings, we have investigated the effects of morphine on ciliary function by measurement of cilia beat frequency *in vitro*, and we have also determined opioid receptor binding in these specimens. We obtained ciliated samples from seven volunteers, and measured cilia beat frequency using the transmitted light technique during exposure to morphine 10 μmol litre^{-1} for 4 h. Mean cilia beat frequency of the samples exposed to morphine was 11.1 (95% confidence interval 10.9–11.5) Hz and that of the controls 11.3 (11.1–11.7) Hz. There was no significant effect of morphine on human cilia beat frequency *in vitro* (MANOVA for repeated measures and nested, $F = 0.61$, $P = 0.66$). In a separate study, we obtained nasal brushings from 20 patients and measured the binding of the opioid antagonist tritiated diprenorphine([^{3}H]DPN). Mean disintegrations per minute (dpm) for total and non-specific binding were 9036 (8105–9967) dpm and 9130 (8054–10206) dpm, respectively. These values did not differ significantly (paired *t* test, $t = 0.22$, $P = 0.83$). We conclude that morphine had no effect on cilia beat frequency *in vitro* and we were unable to demonstrate any significant numbers of opioid receptors on nasal ciliated epithelium. (*Br. J. Anaesth.* 1996; **76**: 274–277)

Key words

Lung, trachea. Analgesics opioid, morphine. Receptors, opioid.

Opioids are potent analgesics that form the mainstay of perioperative pain relief and are widely used as sedatives in the intensive care unit. A variety of such agents, both natural and synthetic, are available, but one of the commonest agents used in these circumstances is morphine. Several studies have reported a depressant effect of morphine on respiratory mucus transport which is one of the most important defences against respiratory tract infections.

In a study of anaesthetized cats in which barium sulphate was insufflated into the lungs, Van Dongen and Leusink found that the administration of morphine 0.5 mg kg^{-1} s.c. delayed the clearance of the radiological marker by a factor of 2–3 times, a distal airways phenomenon [1]. Using a radioactive droplet technique, Forbes and Horrigan measured mucociliary flow in the trachea in dogs. Compared with those respiratory tracts ventilated with 40% nitrous oxide in air, the addition of morphine 6 mg kg^{-1} i.v. reduced mucus transport rates to 70% of controls. This reduction was similar to that found with 1.2 MAC of halothane [2].

Chest infections are one of the commonest forms of serious morbidity after surgery, with an incidence of 6–21% [3–6]. Chest infection is also common in intensive care patients and may develop in about one-third of patients in the ITU [7]. As mucociliary clearance is an important respiratory defence mechanism, its impairment by morphine may have relevance in the postoperative period and in the ITU.

The rate of mucus transport depends on the volume and physical properties of mucus and on the function of the cilia; however, the mechanism by which morphine reduces mucus transport rate has not been elucidated. There are two studies that have investigated the effects of opioids on cilia and have shown a reduction in beat frequency [8, 9]. These studies have been *in vivo* investigations complicated by the administration of other drugs. We have investigated the effects of morphine on human respiratory ciliary function by measuring cilia beat frequency and opioid receptor density using nasal epithelial cell brushings *in vitro*.

Materials and methods

EFFECTS OF MORPHINE ON CILIA BEAT FREQUENCY

After obtaining Ethics Committee approval and informed consent, we obtained samples of ciliated epithelium from seven (six female) non-smoking healthy patients, mean age 40.3 (range 21–56) yr. None of the patients was taking any medication or had an upper respiratory tract infection within the previous 4 weeks. No premedication was given. The samples were acquired by passing a bronchoscopy brush over the inferior nasal turbinates after induction of anaesthesia with propofol 2–3 mg kg^{-1}. The tissue was removed from the brush by agitation in Hanks buffered salt solution (HBSS).

†A preliminary report of part of this study was presented at the Anaesthetic Research Society, London Meeting, November 11–12, 1994 (*British Journal of Anaesthesia* 1995; 74: 484P–485P).

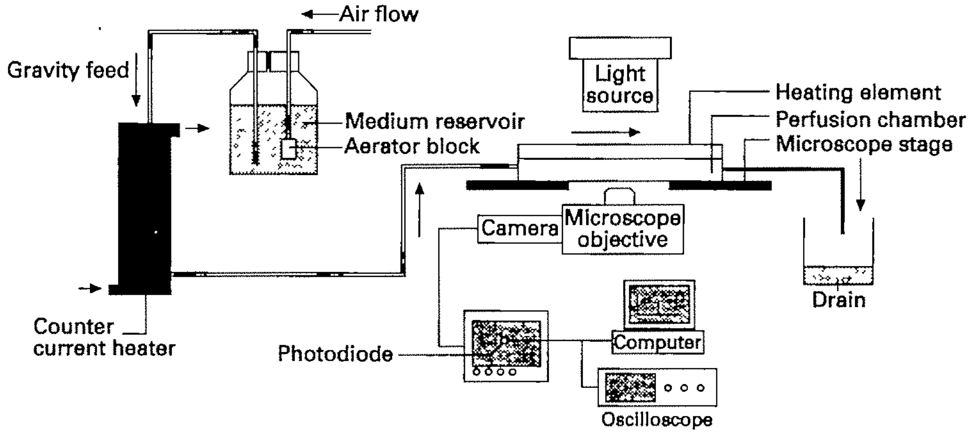

Figure 1 Schematic diagram of the cilia perfusion system.

The ciliated samples from each individual were placed between the coverslips of paired perfusion chambers as described previously [10] (fig. 1). Each chamber was perfused from a separate delivery bottle of HBSS into the entry port of the chamber and out from its exit port into a collecting beaker. HBSS was aerated at 1000 ml min^{-1} and perfused the chambers under the effect of gravity at a constant rate of 0.5 ml min^{-1}. Morphine was added to one delivery bottle in a concentration of 10 μmol litre^{-1}. The observer did not know which chamber received morphine as the delivery tubes from the bottles to the chambers were wound around one another within a countercurrent water jacket. The bottles of HBSS were immersed in a water bath at 37 ($\pm$0.1) °C that also surrounded the countercurrent heat exchanger around the delivery tubing. The perfusion chambers were maintained at 37 °C by means of a thermostatically controlled heating element on the underside of the chamber.

To confirm that morphine was reaching the chamber from the delivery bottle in an adequate concentration, we sampled the perfusate downstream of the perfusion chamber and measured morphine concentrations by high performance liquid chromatography (HPLC). We used an 18C column, 25 cm in length, with phosphate buffer at pH 2 running at 1 ml min^{-1} and electrochemical detection with a carbon electrode. The lower limit of this assay for morphine was of the order of 1 ng ml^{-1} [11].

For measurement of cilia beat frequency we used a photometric method as described previously [10]. This involved detection of ciliary movements using a differential interference contrast microscope (Nikon Diaphot 200) and transmission of the image to a monitoring screen. Cilia beat frequency is determined by their interference with the light reaching a pinhead photodetector attached to the monitoring screen. Voltage changes across the photodetector were amplified to provide a signal on an oscilloscope greater than 0.2 V and low-pass filtered with a cutoff above 25 Hz. Ciliary movements were recorded for a period of 15 s and the voltage changes across the photodetector were digitized and mathematically processed to give a power spectrum. The signals produced by the beating cilia over a 15-s period were divided into three sequential 5-s intervals for analysis. We computed the peak frequency of one power spectrum obtained by calculating the mean of the power spectra for each epoch. A mean of the dominant frequency of each of the three 5-s epochs was then computed. Although shortening the capture time reduced the resolution of measurement to 0.2 Hz, this was not a limiting factor within the experimental conditions used and it increased the confidence interval of the calculated mean beat frequency. The microscope was mounted on a concrete block to minimize interference produced by extraneous vibration.

When the chambers had equilibrated to 37 °C as indicated by the temperature plate on the chamber base, recordings of cilia beat frequency were commenced. Acceptable ciliated edges for measurement were deemed to be those free of mucus, at least 60 μm long and not part of single cells. Readings were taken from both chambers before the addition of morphine and 1, 2, 3 and 4 h after morphine had been added to one chamber by analysing as many acceptable ciliated edges as possible from a minimum of six to a maximum of 12 from each chamber in each defined time band.

At the end of each experiment, it was determined which chamber had received morphine and the samples were discarded. The data approximated to a normal distribution and were analysed by MANOVA for repeated measures and nested using polynomial contrasts, with significance taken at $P <$ 0.05 (SPSS for windows v 5.01).

BINDING OF [^{3}H]DPN TO HUMAN NASAL CILIATED EPITHELIAL CELL MEMBRANES

To determine if opioid receptors were present on cilia, we measured the binding of tritiated diprenorphine, [^{3}H]DPN, a non-selective opioid antagonist, to ciliated epithelial cell membranes [12].

After obtaining Ethics Committee approval and informed patient consent, we collected nasal ciliated epithelial cells on two separate occasions by the methods described earlier. This involved passing a bronchoscopy brush over the inferior nasal turbinates of 10 healthy patients on each occasion after they had received an anaesthetic induction dose of propofol 2–3.3 mg kg^{-1}. The samples were removed from the brushes by agitation in M199. The tissue was washed in Tris HCl 50 mmol litre^{-1}–NaCl 100 mmol litre^{-1}, buffered to pH 7.4. The tissue was homogenized using three 15-s bursts with a tissue tearer and then centrifuged at 13500 rpm for 10 min at 40 °C. This process of homogenization and centrifugation was repeated three times and the cell membranes were then resuspended in 2 ml of the above buffer. Binding studies were performed in 1-ml assay volumes of Tris HCl for 60 min at 37 °C containing a saturating concentration of [^{3}H]DPN 3.7–4.3 nmol litre^{-1}. Non-specific binding was defined in the presence of excess naloxone 10 µmol litre^{-1}.

Bound and free radioactivity were separated by rapid vacuum filtration using a Brandel cell harvester onto Whatman GF/B filters and washed with three 4-ml aliquots of ice cold buffer. After overnight extraction, bound radioactivity was measured by scintillation spectroscopy with Optiphase-X (LKB Wallac) as a scintillant.

Results

We made a total of 739 measurements of cilia beat frequency: 374 from the cilia exposed to morphine and 365 from the controls. Mean cilia beat frequency of the samples exposed to morphine was 11.1 (95% confidence interval 10.9–11.5) Hz and that of the controls 11.3 (11.1–11.7) Hz (MANOVA for repeated measures and nested, $F = 0.61$, $P = 0.66$) (fig. 2).

Mean total and non-specific binding at DPN 3.7–4.3 nmol litre^{-1} were 9036 (8105–9967) dpm and 9130 (8054–10206) dpm, respectively (table 1). These values were not significantly different, indicating no specific binding (paired t test, $t = 0.22$, $P = 0.83$).

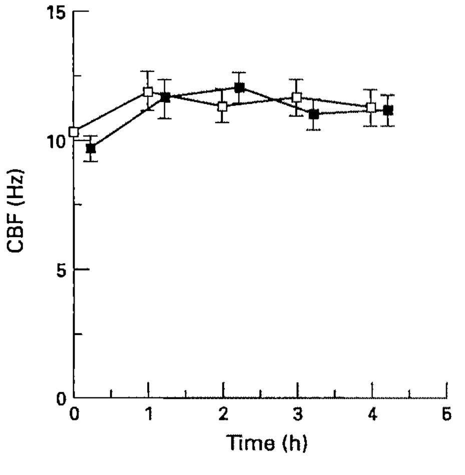

Figure 2 Effects of morphine (■) and control (□) on cilia beat frequency (CBF) (mean (95% confidence interval)).

Discussion

We did not find a significant effect of morphine on cilia beat frequency measured *in vitro* with human nasal cytological samples and were unable to demonstrate the presence of opioid receptors in this tissue.

The variability in the measurements of cilia beat frequency was large. There was greater variability of within-sample measurements than between-sample measurements because of differences in cilia beat frequency between different ciliated edges. Taking n to be the number of ciliated edges measured at any one time, we have computed a *post hoc* power of 80% to detect differences greater than 2 Hz at the 5% level of significance. This represents a change in cilia beat frequency of less than 20%; however, because of the non-linear relationship between cilia beat frequency and mucus transport rate [13], it is possible that small changes in cilia beat frequency may be associated with large changes in mucus transport rate. We elected to investigate binding of opioids to ciliated tissue to substantiate our negative finding.

The concentration we investigated, 10 µmol litre^{-1}, is at the upper limit of the range found in clinical practice, that is the plasma concentration found in patients receiving up to 1500 mg of morphine per day for the treatment of cancer pain [14].

We found an initial small increase in cilia beat frequency in both the control and treatment groups. This may have resulted from the effects of sampling or a delay in the chamber medium equilibrating with temperature.

Studies comparing cilia from the nose with those further down the respiratory tract have found a similar beat frequency [15] and the effects of other drugs on nasal and tracheal tissue are similar [16, 17], suggesting that nasal samples are representative of cilia further down the bronchial tree; however, it is possible that they may not have a similar response to morphine.

There are few comparable studies on the effects of morphine on cilia beat frequency. Rutland, Griffen and Cole measured cilia beat frequency of human nasal brushings with a photometric technique after premedication with the opioid papaveretum and atropine [8]. They found that mean cilia beat frequency in premedicated patients was 11.4 (SD

Table 1 Binding of [^{3}H]DPN to human nasal ciliated cell membranes. No specific binding was detected. Data in each experiment are mean (95% confidence interval) for six determinations of total and NSB in each experiment. Mean values are 12 determinations

		DPN binding (dpm)	
	No. of patients	Total	NSB
Experiment 1	10	8235 (7465–9004)	8106 (6124–10090)
Experiment 2	10	9837 (8129–11544)	10153 (9658–10649)
Mean	20	9036 (8105–9967)	9130 (8054–10206)

1.4) Hz compared with 13.1 (1.9) Hz in a group of awake and unpremedicated controls; this difference was statistically significant ($P < 0.001$). Roth and coworkers used a similar method to directly measure cilia beat frequency *in vitro* from nasal brushings and compared results from the same patients before and after administration of an opioid-containing premedication [9]. The patients received a mixture of morphine 5–10 mg i.v., atropine 1 mg i.m. and 2% lignocaine 2–3 ml applied topically to the nose. The authors found a small but significant reduction in ciliary beat frequency after medication from a mean of 12.2–11.0 Hz. In both of these studies, the addition of other drugs limits interpretation. Although low doses of lignocaine do not affect ciliary beat frequency *in vitro* [18], 2% lignocaine has been shown to cause ciliostasis in human nasal biopsy specimens [19]. Atropine is known to inhibit mucus transport rates in humans [20]; however, this appears to be caused by inhibition of mucus secretion and there is little direct evidence for a depressant effect on the cilia [21].

Another explanation for the conflict in our results with those described above may relate to differences in methods. We elected to measure cilia beat frequency from all visible edges whereas other workers appear to have measured the fastest beating ciliated edges. Consequently, the variation in our measurements was large; however, selection of certain ciliated edges, as used by other workers, introduces a bias that we avoided.

Using [^{3}H]DPN at a concentration that would occupy all opioid receptors, we failed to demonstrate any specific binding (receptors) on nasal ciliated epithelial cell membranes. This concurs with our *in vitro* findings of the absence of effects of morphine on cilia beat frequency.

The mechanisms by which morphine reduces mucociliary transport *in vivo* remain to be elucidated. They may be related to effects on mucus or to *in vivo* effects on the cilia. Rogers and Barnes showed that morphine reduced mucus secretion stimulated by capsaicin in bronchitic patients [22]. One could speculate that during anaesthesia which involves procedures and agents that are irritant to the airways, morphine might similarly inhibit mucus secretion. Reduction in the secretion of mucus and its subsequent movement might alter its physical properties which would affect the function of the cilia, an effect that would not be observed with mucus-free *in vitro* preparations.

Although there is no evidence for neural control of ciliary function in humans, there are free nerve endings adjacent to the basement membrane [23]. An alternative hypothesis is that morphine may have an effect on cilia *in vivo* because of effects on neural connections which are absent from *in vitro* preparations.

Electromyographic and mechanomyographic characteristics of neuromuscular block by magnesium sulphate in the pig†

C. LEE, X. ZHANG AND W.-F. KWAN

Summary

In spite of its well known propensity to cause accidental paralysis by a specific mechanism of action, Mg^{2+}-induced neuromuscular block has not been examined systematically for its characteristics of muscle response to nerve stimulation. We examined in seven anaesthetized domestic pigs the mechanomyographic (MMG) and neurally evoked compound electromyographic (ncEMG, EMG) responses of the tibialis anterior muscle to stimulation of its motor nerve, at baseline and during three levels of neuromuscular block induced by infusion of $MgSO_4$ (at approximately 25%, 50% and 75% depression of the 0.1-Hz EMG). We observed that: at 0.1 Hz, the MMG tended to be more depressed than the EMG; the train-of-four (2 Hz) was essentially non-fading; the tetanic force (50 Hz) showed tetanic ascent instead of tetanic fade and reached its baseline control value at 5 s in spite of depression of the twitch; the EMG counterpart of the tetanus showed escalation of the train of ncEMG, so that the fourth ncEMG was much greater than the first; and the post-tetanic twitch was also relatively spared from Mg^{2+}-induced neuromuscular block. Sparing of the tetanus and post-tetanic twitch resulted in large gains in the tetanus:twitch ratio and the post-:pre-tetanic twitch ratio, which increased at the 75% level of depression from 2.8 (SD 0.7) to 11.5 (4.0), and from 1.5 (0.3) to 4.6 (1.4) ($P < 0.01$), respectively. These characteristics of neuromuscular block by Mg^{2+} reflect its prejunctional mechanism of action by depression of transmitter release. (*Br. J. Anaesth.* 1996; **76**: 278–283)

Key words

Ions, magnesium. Neuromuscular block, measurement of response. Measurement technique, mechanomyography. Measurement technique, electromyography. Pig.

The non-depolarizing neuromuscular block produced by blockers of the curare-type ("curariform") is recognized by train-of-four (TOF) fade, tetanic fade and post-tetanic enhancement of twitch response ('post-tetanic potentiation'). In comparison, depolarizing neuromuscular block does not manifest fade or post-tetanic potentiation, but the changing nature of its block from phase I to phase II is recognized by these signs [1, 2]. Between the non-depolarizing and depolarizing blocks, mechanomyographic (MMG) and electromyographic (EMG) responses to motor nerve stimulation differ in relative sensitivity [1]. Fade observed during curariform neuromuscular block *in vivo* is generally attributed to diminution of successive end-plate potentials (EPP) observed *in vitro*, which in turn is attributed to depression of acetylcholine mobilization prejunctionally [3]. TOF fade [4] has yielded the "TOF count" [5], a method which is now used as a routine to estimate curariform neuromuscular block clinically. The diminishing TOF ratio during continuous administration of suxamethonium is also useful in defining phase II *vs* phase I neuromuscular block [2, 6]. At the end of surgery, these monitoring techniques also guide dosing and reversal of neuromuscular block in anaesthetic practice.

In contrast with the extensive literature on curariform and depolarizing neuromuscular blocks, there is a remarkable paucity of literature on the features of magnesium-induced neuromuscular block *in vivo*. Many reports have documented accidental paralysis as a side effect of magnesium sulphate ($MgSO_4$) therapy [7]. Magnesium (Mg^{2+}) blocks prejunctionally, with a different mechanism of action from the curariform and depolarizing blockers.

As indications for $MgSO_4$ therapy have increased rapidly [8, 9], we feel that Mg^{2+} deserves an independent study of its neuromuscular blocking characteristics. We have recently quantified the dose–response relationship of Mg^{2+}-induced neuromuscular block in an animal model while studying the effect of Mg^{2+} on the refractoriness of neuromuscular transmission [10]. The present study describes in qualitative and quantitative terms the MMG and EMG responses to motor nerve stimulation during three levels of Mg^{2+}-induced neuromuscular block.

Materials and methods

With institutional approval, seven male Duroc brown pigs, 9–12 kg, were anaesthetized with pentobarbitone 50 mg kg^{-1} i.p., supplemented with

† Presented in part at the Annual Meeting of the American Society of Anesthesiologists, October 24, 1995, Atlanta, Georgia, USA.

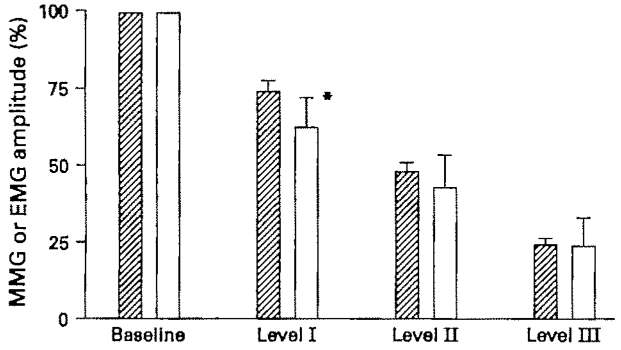

Figure 1 Differential depression by Mg^{2+} of the neurally evoked 0.1-Hz MMG (□) and EMG (▨) responses from their respective baselines at approximately 25 % (level I), 50 % (level II) and 75 % (level III) depression of the ncEMG.

2–5 mg kg^{-1} i.v. as required during the study. A cuffed tracheal tube of 6-mm internal diameter was inserted and ventilation of the lungs was controlled with a Harvard respirator pump at a rate of 15 times per minute. Tidal volume of air was adjusted to maintain an end-expiratory carbon dioxide concentration of 4–4.5 %. A cannula was inserted into a carotid artery for continuous monitoring of arterial pressure. A peripheral venous cannula was inserted for hydration and infusion of $MgSO_4$. Each pig received approximately 120–180 ml of 5 % glucose in normal saline during the entire experiment. The oesophageal temperature was maintained at 36–38 °C by a heating lamp. A pair of fine Grass EEG platinum solid needle electrodes (type E2) were inserted s.c., slightly posterior and distal to the proximal head of the fibula. Several attempts were made to position these electrodes close together (1–2 mm at the tips) and as close to the common peroneal nerve as possible, so that the electrical stimulus required for supramaximal stimulation and the stimulus artefact were as small as possible.

Three other identical electrodes were used for detection of the neurally evoked compound electromyogram (ncEMG), as described previously [11]. Guided by palpation of the twitch, the sensing electrode was inserted s.c. along the frontal aspect of the tibialis anterior muscle, crosswise to the muscle at its belly. A reference electrode was inserted s.c. near the insertion of this muscle, away from all muscles. A reference electrode was inserted s.c. between the stimulating and sensing pairs of electrodes. The EMG sensing electrode was repositioned several times to assure an optimal waveform, without double peaking or excessive stimulus artefact. Each preparation must produce a stable unipolar waveform typical of the ncEMG, as described previously [11], before the experiment can begin. The electric stimuli were generated by a Grass S88 stimulator and passed through a Grass SIU5 stimulus isolation unit. The supramaximal stimulus was determined, and 20–50 % of the voltage added. The stimulus was rectangular and of 0.1 ms duration. The ncEMG response was digitized, processed and reconverted to analogue waveforms for immediate online recording, as described previously [12]. Side by side with the ncEMG, the MMG response of the same tibialis anterior muscle was recorded simultaneously. The tendon was detached from its insertion with a chip of bone, freed from constraints and connected to a Grass force displacement transducer (FT10C). The motor nerve was stimulated at 0.1 Hz. Periodically (see below) the 0.1-Hz stimulation was interrupted for TOF (2 Hz) and tetanic (50 Hz, 5 s) stimulations. The first post-tetanic 0.1-Hz stimulation was delivered 5 s after the tetanus. Of the 250 ncEMG responses corresponding to a 50-Hz, 5-s tetanus, the first four could be processed and recorded in time before the first post-tetanic twitch was evoked. These four were recorded online for analysis.

After the preparation had stabilized for 30–45 min,

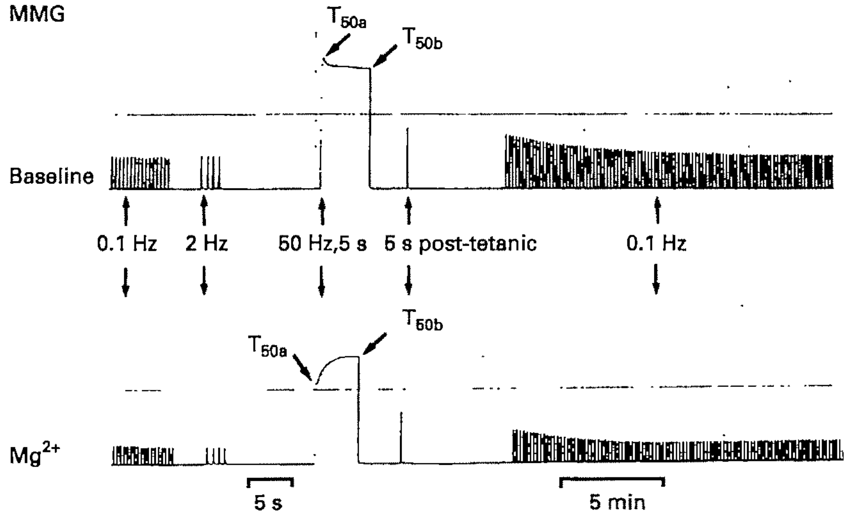

Figure 2 Neurally evoked MMG twitch (0.1 Hz), TOF (2 Hz), tetanus (50 Hz, 5 s) and post-tetanic twitches at baseline (upper panel) and during Mg^{2+}-induced neuromuscular block (lower panel). Note the increasing tetanus ("tetanic ascent") during neuromuscular block. In this experiment, the 0.1-Hz twitch was depressed by 45 %. TOF responses neither clearly faded nor escalated at baseline or during block. The tetanus was sustained at baseline. It was depressed by 32 % during block, but increased steadily so that at 5 s it was depressed by only 11 % from baseline. The post-tetanic twitch was potentiated at baseline. The potentiation was augmented during block, so that the post-tetanic twitch was depressed by only 16 % from baseline.

baseline values of a series of EMG and MMG responses were obtained. The series consisted of 0.1 Hz ("twitch"), TOF, tetanic and post-tetanic responses. $MgSO_4$ was then infused to establish three levels of neuromuscular block in succession, at approximately 25%, 50% and 75% depression of the 0.1-Hz EMG. Each level, when established, was maintained 5–10 min at the end of which a series of twitch, TOF, tetanic and post-tetanic responses were again obtained. Because various EMG and MMG variables of response were expected to differ, the three levels of neuromuscular block were established according to the amplitude of the 0.1-Hz EMG, irrespective of other variables. Levels I, II and III therefore refer to approximately 25%, 50% and 75% depression of the amplitude of the 0.1-Hz ncEMG, respectively. Data are expressed as mean (SD), and paired data sets were compared with repeat measures ANOVA or Student's paired t test (two-tailed). $P < 0.05$ was considered statistically significant.

Results

The three levels of neuromuscular block actually established were 25 (3)%, 51 (3)% and 74 (2)% depression of the ncEMG, respectively (fig. 1). The MMG twitch response tended to be more depressed than the EMG counterpart. Figure 2 illustrates the MMG twitch, TOF, tetanic and post-tetanic twitch responses at baseline and during Mg^{2+}-induced neuromuscular block. Figure 3 illustrates the EMG counterparts. The TOF ratio at control was 1 with every experiment. The TOF responses remained non-fading in character during all levels of Mg^{2+}-induced neuromuscular block, although the EMG and MMG TOF ratios were both slightly but consistently diminished from 1 ($P < 0.05$) to approximately 0.9.

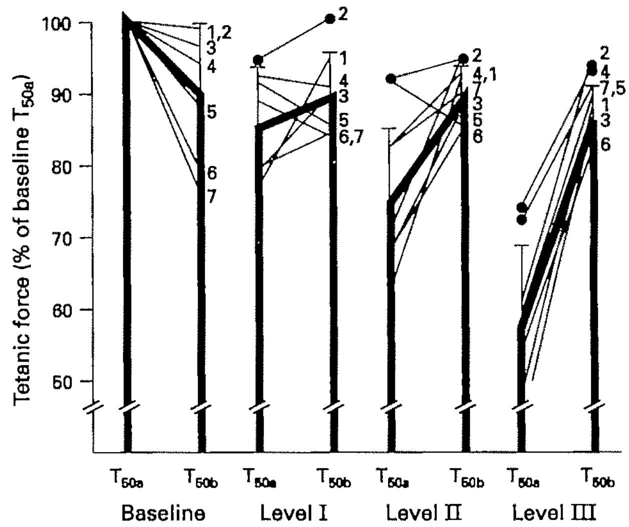

Figure 4 Tetanic ascent observed during Mg^{2+}-induced neuromuscular block. The thick line = the 5-s tetanus; the vertical error bars = SD. T_{50a} and T_{50b} = tetanic force at the beginning and end of the 5-s, 50-Hz tetanus, respectively. The thin numbered horizontal or slanting lines = individual pigs. Level tetanus at baseline (pigs 1, 2) ascended with any neuromuscular block, while fading tetanus at baseline (pigs 5, 6, 7) reversed at deeper levels of block to show an ascent.

Mg^{2+}-induced neuromuscular block did not cause tetanic fade. Instead, it caused a tetanic increase so that the tetanic contractile force was greater at 5 s (fig. 2, T_{50b}) than at the beginning of tetanus (fig. 2, T_{50a}). Figure 4 shows the varied behaviour of the tetanus among pigs. Some pigs showed mild tetanic fade at baseline, which reversed at various levels of neuromuscular block to become a tetanic increase. At deeper levels of block, all pigs showed marked tetanic increase. Corresponding with the tetanic ascent, the fourth ncEMG of the tetanus was much greater in amplitude than the first during neuromuscular block (fig. 3, 50 Hz; fig. 5).

The tetanus was spared from Mg^{2+}-induced neuromuscular block (fig. 6). Comparing the contractile forces at 5 s (T_{50b}), the tetanus elicited during $MgSO_4$ infusion did not show a statistically significant difference from the tetanus elicited at baseline ($P > 0.5$ for all three levels). The post-tetanic twitch was also spared markedly, although not completely.

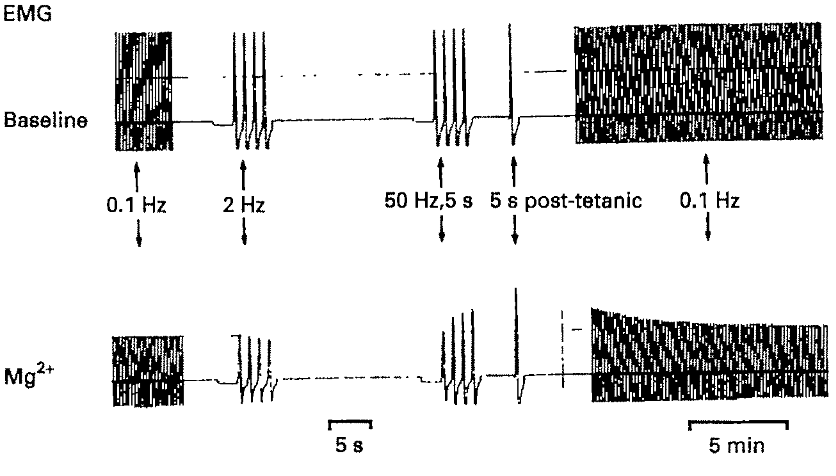

Figure 3 Neurally evoked compound EMG responses at baseline (upper panel) and during Mg^{2+}-induced neuromuscular block (lower panel). The TOF responses (2 Hz) did not fade at baseline but faded slightly during block. The next four ncEMG responses, marked "50 Hz, 5 s", represent the first 80 ms of the 5-s tetanus. They showed marked escalation during neuromuscular block. This escalation is the EMG counterpart of the increasing tetanic force. As is in the case of the MMG, the 5-s post-tetanic twitch was less depressed than the pre-tetanic twitch. The 50 Hz and 2 Hz EMG were displaced with the same spacing for clarity [11, 12].

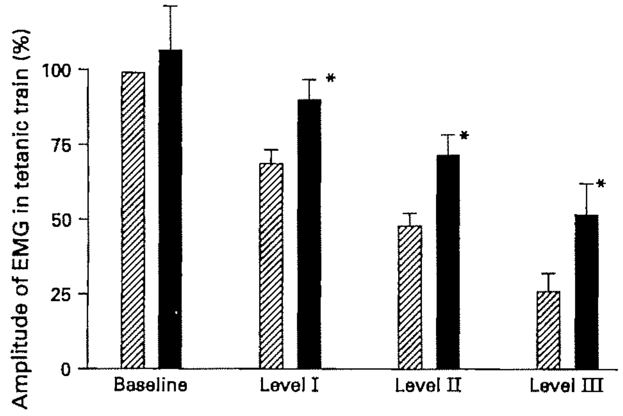

Figure 5 The first (▨) and fourth (■) of the train of ncEMG of a tetanus (50 Hz) evoked at baseline and at three levels of Mg^{2+}-induced neuromuscular block. At each level, the first ncEMG corresponds to the singly evoked ncEMG (0.1 Hz) and shows the degree of neuromuscular block. The fourth ncEMG was relatively spared from the block. The fourth : first ratio increased from 1.1 (0.2) to 1.3 (0.1), 1.5 (0.1) and 2.0 (0.2) at the three levels of block, respectively ($P < 0.05$). The discrete EMG escalated as the fused tetanic contraction ascended.

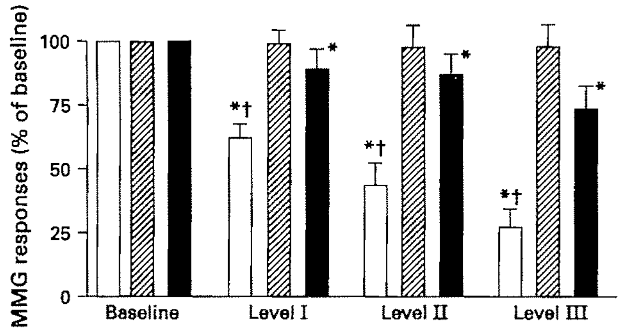

Figure 6 Sparing of tetanus (▨) and post-tetanic twitch (■) from Mg^{2+}-induced neuromuscular block. Tetanic force (50 Hz, 5 s) was measured at 5 s, as the T_{50b}. The post-tetanic twitch was evoked 5 s after the end of the tetanus. Note that the tetanic force measured at 5 s did not diminish from baseline ($P > 0.5$, all three levels) in spite of depression of the twitch (□). The post-tetanic twitch was slightly depressed from baseline ($P < 0.05$), but less so than the twitch at any level ($P < 0.01$).

As a result of tetanic and post-tetanic sparing, the tetanus : twitch ratio and post- : pre-tetanic twitch ratio were increased markedly (table 1).

Discussion

There is a clear distinction between prejunctional and postjunctional sites of action and between mobilization and release mechanisms of the prejunctional actions of neuromuscular blocking agents. For decades, Mg^{2+} has been recognized as the prototype of the latter mechanism of prejunctional neuromuscular block *in vitro* [13]. It causes accidental paralysis by itself or in interaction with other neuromuscular blockers *in vivo*. In addition to obstetric use, Mg^{2+} is being used increasingly by paediatricians [14], endocrinologists [15], cardiologists [16–19], cardiac surgeons [20] and emergency [21, 22] and other specialists [8, 23]. Examples of new indications for $MgSO_4$ which are of interest to anaesthetists are phaeochromocytoma [24–26], refractory cardiac arrhythmia [16] and resuscitation [21, 22]. A method of diagnosis of Mg^{2+}-induced neuromuscular block by nerve stimulation therefore deserves exploration.

According to our results, Mg^{2+}-induced neuromuscular block may be characterized as follows: the MMG response tends to be more depressed than the EMG response; TOF responses do not fade; tetanus does not fade, instead its contractile force increases; the train of successive EMG responses during tetanic stimulation escalate; the peak tetanic force does not diminish although the tetanus starts at a lower point; and the physiological potentiation of the post-tetanic twitch is augmented so that the post-tetanic twitch is relatively spared. As a result of tetanic and post-tetanic sparing, the tetanus : twitch ratio and the post- : pre-tetanic twitch ratio increase markedly This set of characteristics clearly distinguish Mg^{2+}-induced neuromuscular block from curariform, phase I (depolarizing), phase II (post-depolarizing, desensitization) and post-junctional irreversible non-depolarizing (α-bungarotoxin) types of neuromuscular block [27] (table 2).

TOF fade is explained by diminution in successive EPP, which result from depressed mobilization of the transmitter, which in turn is caused by occupation of the prejunctional "mobilization receptors", according to Bowman [3]. This theory requires that neuromuscular block achieved by occupation of postjunctional receptors alone, such as by .α-bungarotoxin, does not manifest tetanic or TOF fade. This, indeed, is the case [27]. In the case of Mg^{2+}, our observations are explicable by the generally accepted main mechanism of neuromuscular action of Mg^{2+}, which is depression of prejunctional release of acetylcholine. As successive motor impulses lead to accumulation of Ca^{2+} in the motor nerve terminal, successive EPP become less depressed by Mg^{2+}. This escalation of the train of EPP results in "tetanic escalation" of the ncEMG responses. It also causes the increasing tetanic force ("tetanic ascent") which spares the tetanus from depression. The enhanced post-tetanic potentiation can similarly be explained by accumulation of Ca^{2+} during tetanic stimulation. The MMG twitch tends to be more depressed than its corresponding EMG because Mg^{2+} is also thought to directly depress the contractility of the muscle [13]. The reason for the slight TOF fade is unclear. Ramanathan and colleagues [28] reported TOF escalation in pre-eclamptic patients. Toxaemia of pregnancy may account for the difference. In any case, the TOF ratio did not change by more than 10% from baseline.

From the above, it becomes obvious that the word "non-depolarizing" is generic and fails to distinguish prejunctional (mobilization, release) and postjunctional (competitive, non-competitive) non-depolarizing neuromuscular blocks from curariform (mobilization and competitive) block (table 2). Because of this, we prefer to call neuromuscular block of the curare type "curariform" block, to facilitate its distinction from other types of non-depolarizing neuromuscular block, including the "release block" by Mg^{2+}.

Table 1 Tetanus and post-tetanic twitch, as multiples of the pre-tetanic twitch, during 25% (level I), 50% (level II) and 75% (level III) Mg^{2+}-induced depression of the 0.1-Hz ncEMG. *$P < 0.05$: level I, II or III *vs* baseline values, both rows

	Baseline	Level I	Level II	Level III
Tetanus: twitch ratio*	2.7 (0.7)	4.6 (1.7)	6.7 (2.7)	11.5 (4.3)
Post-: pre-tetanic twitch ratio	1.5 (0.3)	2.2 (0.6)	3.0 (0.9)	4.6 (1.4)

Table 2 Patterns of mechanomyographic neuromuscular responses to nerve stimulation distinguishing various mechanisms of neuromuscular block *in vivo*

	$MgSO_4$	Phase I	Phase II	Curariform	α-Bungarotoxin
MMG *vs* EMG	More sensitive	Less sensitive	?	More sensitive	?
TOF fade	Negligible	Negligible	Emerges	Marked	Negligible
Tetanus	Increases	Level	Fade emerges	Fades	Level
Tetanus sparing	Marked	?	?	Clear	?
Post-tetanic twitch potentiation	Marked	Minimal	Emerges	Marked	Clear

The clinical implications of our observations can only be speculative at present, and only a few obvious possibilities are examined below. First, neuromuscular block by the same mechanism of action should exhibit similar or the same patterns of response to nerve stimulation. Aminoglycoside antibiotics block neuromuscular transmission mainly by competition with Ca^{2+}, as is the case with Mg^{2+} [29, 30]. In agreement with this, we have previously observed that streptomycin and neomycin also block neuromuscular transmission with tetanus and post-tetanic sparing [31]. We surmise that the extremely high mortality associated with antibiotic-induced neuromuscular block in the 1970s might be partially attributable to failure to differentially diagnose aminoglycoside-induce neuromuscular block from curariform or depolarizing neuromuscular block [32].

Second, humans usually exhibit similar qualitative patterns of neuromuscular block as do most laboratory animals. Quantitatively, domestic pigs are useful for predicting human responses to neuromuscular blocking agents [33, 34]. As escalation of the train of ncEMG responses in the beginning of tetanus is a consistent and clear-cut finding, a very brief burst of nerve stimuli delivered rapidly might be the best candidate for clinical development as a diagnostic tool of Mg^{2+}-induced neuromuscular block. Such a brief single burst of stimulation should cause no greater pain than the double-burst stimulation. Similar to the TOF [4] or count [5], the escalation ratio and the tetanus: twitch ratio require no historical control for quantitative assessment of neuromuscular block.

Third, tetanic sparing should imply that in spite of depression of the twitch, physiological muscle functions, all of which are tetanic in nature, may be well preserved. The fact that the tetanic force takes a few seconds to reach maximum may imply that sustained motions such as headlift or breathing may be less depressed than brisk motions such as knee jerk or cough. Indeed, toxaemic patients are often given $MgSO_4$ until the knee jerk disappears, without obvious loss of ability to lift the head and to breathe. On the one hand, therefore, tetanic sparing represents a margin of safety of physiological functions. On the other hand, however, this pattern of paresis may lead to failure to observe Mg^{2+}-induced neuromuscular block clinically, which is a danger. Finally, in a patient who has previously received both $MgSO_4$ and a curariform blocker, detection of TOF and tetanic fades should reveal the continuous presence of the curariform block while demonstration of a tetanic ascent should imply dominance of Mg^{2+}-induced neuromuscular block. A level tetanus may imply absence of any neuromuscular block or a balance of tetanic fade and tetanic ascent.

A model to describe the rate of oxyhaemoglobin desaturation during apnoea

A. D. FARMERY AND P. G. ROE

Summary

We have developed a model to describe the rate of oxyhaemoglobin desaturation during apnoea. This model takes into account the non-steady-state kinetics which pertain to this situation. We first derived a mathematical expression for instantaneous oxygen flux rate from the alveolar compartment. We then derived an expression to describe the effect of shunt on this flux. The effect of circulation time on real-time arterial mixed venous oxygen content difference and oxygen flux in the lung was determined graphically. We finally described a manoeuvre to accommodate the effect of the Bohr shift which is related to the increase in $F\text{A}_{CO_2}$ during apnoea. We present plots of arterial oxyhaemoglobin saturation (Sa_{O_2}) *vs* duration of apnoea to illustrate the individual effects of the initial fractional concentration of oxygen in the alveolus ($F\text{A}_{O_2(initial)}$), alveolar volume ($V\text{A}$), shunt fraction ($\dot{Q}\text{S}/\dot{Q}\text{T}$), oxygen consumption rate ($\dot{V}O_2$), total blood volume ($Q\text{T}$) and haemoglobin concentration (Hb). The model is illustrated by examples of paediatric, morbidly obese and postoperative scenarios. The postoperative scenario is particularly notable for the effect of a combination of small changes in individual variables leading to a large overall effect on the rate of oxyhaemoglobin desaturation. (*Br. J. Anaesth.* 1996; **76**: 284–291)

Key words

Oxygen, saturation. Ventilation, apnoea. Model, pharmaco-physiological.

Apnoea may occur both during anaesthesia and in the postoperative period for many reasons. The principal consequence of this depends on the rate at which the oxyhaemoglobin saturation of arterial blood (Sa_{O_2}) is reduced to unacceptable levels and there are clearly many relevant factors. In order to study the factors affecting the rate of oxyhaemoglobin desaturation, it was necessary to construct a model.

It might appear *a priori* that the rate at which oxyhaemoglobin desaturation occurs is simply determined by the ratio of the oxygen consumption rate ($\dot{V}O_2$) to the alveolar reserve volume of oxygen ($V\text{A}$). However, such a model is too simplistic and has been criticized [1] because it is based on steady-state kinetics, and apnoea is a non-steady state event. In the non-steady state, the rate of oxygen flux from the alveoli to the pulmonary capillaries is not constant and the shunt equation is not easily soluble. There is also a time lag between changes in arterial oxygen content and corresponding changes in mixed venous oxygen content because of the circulation time which affects the rate of alveolar oxygen exchange at any time. In addition to the alveolar oxygen volume at the beginning of apnoea, circulating blood also serves as an oxygen store which is in a dynamic equilibrium with the diminishing alveolar store. The reduction in Sa_{O_2} is moderated by the reservoir of oxygen in the alveoli.

The obligatory increase in arterial carbon dioxide partial pressure (Pa_{CO_2}) and the consequent decrease in pH during apnoea has an effect on the oxygen–haemoglobin dissociation curve (ODC) such that the affinity of haemoglobin for oxygen varies as a function of time throughout apnoea (dynamic Bohr shift). This too might be expected to affect the rate of oxyhaemoglobin desaturation.

We therefore present a comprehensive model which incorporates the above considerations to describe the rate of arterial oxyhaemoglobin desaturation in the non-steady state in various pathophysiological states.

Theoretical considerations

We made several assumptions in constructing the model. We assumed that lung volume remains constant during apnoea. In fact, lung volume diminishes slightly during apnoea because oxygen is removed to a slightly greater extent than carbon dioxide accumulates, assuming that the value of the respiratory quotient is < 1. A three-compartment model of shunt, ideal alveoli and deadspace was used to model the lung. Gas mixing was assumed to be complete within the ideal alveoli. Circulation of blood was modelled as a single unit of given mean transmit time (Δt_c) in which no mixing of blood occurs.

In the equations which follow, unless otherwise stated, all gas and blood volumes are expressed in litres, time is expressed in minutes and gas partial pressures are expressed as fractions of one standard atmosphere (101.325 kPa, BTPS) and are dimensionless. Haemoglobin concentration (Hb) is ex-

pressed in g litre^{-1}. The dimensions of terms with compound units such as flow and gas contents are expressed in terms of the primary dimensions listed above. $K\mathrm{h}$ = Hüfner constant (1.34×10^{-3} litre g^{-1}). All fractional concentrations (F) refer to oxygen and all saturations (S) refer to arterial oxyhaemoglobin, unless otherwise stated.

AN EXPRESSION FOR THE INSTANTANEOUS OXYGEN FLUX RATE FROM THE ALVEOLAR COMPARTMENT

Let the quantity of oxygen in the apnoeic lung be ($V\mathrm{A} \times F\mathrm{A}$) where $V\mathrm{A}$ = alveolar volume and $F\mathrm{A}$ = fractional concentration of oxygen in alveolar gas ($F\mathrm{A}_{\mathrm{O}_2}$).

The rate of change of oxygen mass ($\dot{v}\mathrm{O}_2$)

$$= \mathrm{d}(V\mathrm{A} \times F\mathrm{A})/\mathrm{d}t$$

$$= V\mathrm{A} \times \mathrm{d}F\mathrm{A}/\mathrm{d}t + F\mathrm{A} \times \mathrm{d}V\mathrm{A}/\mathrm{d}t$$

It is important to appreciate that the term $\dot{v}\mathrm{O}_2$ = the instantaneous rate of oxygen uptake by the blood. It is a *variable* and a function of time. Only in the steady state is the term constant and equal to the term $\dot{V}\mathrm{O}_2$, the oxygen consumption rate in the tissues. As we have assumed that $V\mathrm{A}$ remains constant, $\mathrm{d}V\mathrm{A}/\mathrm{d}t$ equals zero and hence:

$$\dot{v}\mathrm{O}_2 = -V\mathrm{A} \times \mathrm{d}F\mathrm{A}/\mathrm{d}t \tag{1}$$

Notice the sign change resulting from the convention that oxygen uptake by the blood is nominally positive, and $\mathrm{d}F\mathrm{A}/\mathrm{d}t$ is negative.

AN EXPRESSION TO DESCRIBE THE EFFECTS OF SHUNT

The relatively small quantity of oxygen physically dissolved in blood has been ignored in order to simplify the mathematical analysis. In all cases, the error in predicted $S\mathrm{a}_{\mathrm{O}_2}$ incurred by this omission is less than 0.05%, although this is greater when the inspired fractional concentration of oxygen ($F\mathrm{I}_{\mathrm{O}_2}$) is 1 and under hyperbaric conditions.

The shunt fraction ($\dot{Q}\mathrm{s}/\dot{Q}\mathrm{T}$) = f_s

Then,

$$S\mathrm{a} = S\mathrm{c}' \times (1 - f_s) + f_s \times S\bar{\mathrm{v}} \tag{2}$$

where $S\mathrm{c}'$ = end-capillary oxyhaemoglobin saturation and $S\bar{\mathrm{v}}$ = mixed venous oxyhaemoglobin saturation, $\dot{Q}\mathrm{s}$ = shunted blood flow and $\dot{Q}\mathrm{T}$ = total cardiac output.

From Fick's principle,

$$\dot{v}\mathrm{O}_2 = \dot{Q}\mathrm{T} \times (\mathrm{Hb}) \times K\mathrm{h} \times (S\mathrm{a} - S\bar{\mathrm{v}})$$

$$S\bar{\mathrm{v}} = S\mathrm{a} - \dot{v}\mathrm{O}_2/\dot{Q}\mathrm{T} \times (\mathrm{Hb}) \times K\mathrm{h} \tag{3}$$

Combining equations (2) and (3) to eliminate $S\bar{\mathrm{v}}$,

$$S\mathrm{a} = S\mathrm{c}' - \left(\frac{f_s}{1 - f_s}\right) \times \frac{\dot{v}\mathrm{O}_2}{\dot{Q}\mathrm{T} \times (\mathrm{Hb}) \times K\mathrm{h}}$$

Let $S\mathrm{c}'$ be expressed in terms of $F\mathrm{A}$ (see appendix) and substituting $\dot{v}\mathrm{O}_2$ from equation (1) gives:

$$S\mathrm{a} = b \times \left(\frac{F\mathrm{A}^n}{F\mathrm{A}^n + F_{50}{}^n}\right) - \left(\frac{f_s}{1 - f_s}\right) \times \frac{V\mathrm{A} \times \mathrm{d}F\mathrm{A}/\mathrm{d}t}{\dot{Q} \times (\mathrm{Hb}) \times K\mathrm{h}} \tag{4}$$

This differential equation describes $S\mathrm{a}$ as a function of $F\mathrm{A}$ and $\mathrm{d}F\mathrm{A}/\mathrm{d}t$, both of which are functions of time. It is not yet soluble for $S\mathrm{a}$ in terms of time alone, as we have no independent expression of the time course of $F\mathrm{A}$. This problem is addressed in the next section.

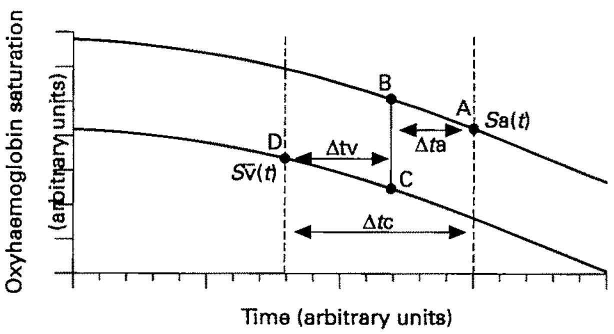

Figure 1 Putative time courses of "tissue arterial" (upper curve) and "tissue venous" (lower curve) oxyhaemoglobin saturation during apnoea (see text for further explanation).

CONSIDERATION OF THE TIME COURSES OF ARTERIAL AND VENOUS OXYHAEMOGLOBIN DESATURATION AT ANY PARTICULAR LOCUS

Oxyhaemoglobin saturation after the onset of apnoea may be thought of as having three dimensions; it varies not only with time, but also with its position within the circulation, and so has a spatial dimension. For example, at a time when arterial blood is just starting to desaturate in the lungs, blood "sampled" at a peripheral arterial site just proximal to the tissues is not yet desaturated because of the circulation time lag. Figure 1 shows a putative plot of the time courses of arterial and venous oxyhaemoglobin desaturation. These two-dimensional curves represent the oxyhaemoglobin saturation at tissue arterial (upper curve) and tissue venous (lower curve) loci, respectively, as time from the start of apnoea varies. This same diagram can be used to consider the spatial dimension of apnoeic desaturation. The X axis now no longer represents ***absolute*** apnoeic time, but the ***relative*** time from when saturation began to decrease at any particular locus. Thus points A, B, C and D which represent the *contemporaneous* saturation at four loci within the circulation are not aligned vertically because the transit times to these various loci are different. Point A represents the saturation of blood in the most proximal part of the arterial tree (pulmonary venous) at time t which is equal to $S\mathrm{a}(t)$. Point B represents the saturation of blood at the most distal part of the arterial tree (just proximal to the lumped tissues) at time t. Point C represents the saturation of blood at the most proximal part of the venous tree (just distal to the lumped tissues) at time t. Point D represents the saturation of blood at the most distal point of the venous tree (pulmonary arterial) at time t which is equal to $S\bar{\mathrm{v}}(t)$. The arterial and venous curves are separated by vertical displacement equal to $\dot{V}\mathrm{O}_2/\dot{Q}\mathrm{T} \times (\mathrm{Hb}) \times K\mathrm{h}$ which is derived from Fick's principle (i.e. equation (3) applied at the tissue level). The horizontal distance between A and B is the arterial transit time ($\Delta t\mathrm{a}$) and between C and D is the venous transit time ($\Delta t\mathrm{v}$). The total circulation time, $\Delta t\mathrm{c} = \Delta t\mathrm{a} + \Delta t\mathrm{v}$.

By inspection, mixed venous saturation at time t can be seen to be as follows:

$$S\bar{v}(t) = Sa(t-\Delta tc) - \frac{\dot{V}O_2}{\dot{Q}T \times (Hb) \times Kh} \qquad (5)$$

Any function with a fixed phase shift such as $Sa(t-\Delta tc)$ can be expressed in terms of the same function with zero shift, that is $Sa(t)$, using Taylor's expansion as follows:

$$Sa(t-\Delta tc) = Sa(t) - \Delta tc \times \frac{dSa(t)}{dt} - \frac{\Delta tc^2}{2!} \times \frac{d^2Sa(t)}{dt^2} + \ldots \qquad (6)$$

So the *contemporaneous*, real-time arterial mixed venous oxyhaemoglobin saturation difference in the lung can be expressed as follows by combining equations (5) and (6):

$$Sa(t) - Sv(t) = \Delta tc \times \frac{dSa(t)}{dt} + \frac{\Delta tc^2}{2!} \times \frac{d^2Sa(t)}{dt^2} + \frac{\dot{V}O_2}{\dot{Q}T \times (Hb) \times Kh}$$

Fick's principle dictates that this saturation difference, when multiplied by the product of cardiac output, haemoglobin concentration and Huffner constant equals the instantaneous oxygen flux ($\dot{v}O_2$) from the alveolus to the pulmonary capillary blood at time t.

Hence,

$$\dot{Q}T \times (Hb) \times Kh \times \left(\Delta tc \times \frac{dSa(t)}{dt} + \frac{\Delta tc^2}{2!} \times \frac{d^2Sa(t)}{dt^2} + \frac{\dot{V}O_2}{\dot{Q}T \times (Hb) \times Kh}\right) = \dot{v}O_2 \qquad (7)$$

Combining equations (1) and (7) we have:

$$\Delta tc \times \frac{dSa(t)}{dt} + \frac{\Delta tc^2}{2!} \times \frac{d^2Sa(t)}{dt^2} + \frac{\dot{V}O_2}{\dot{Q}T \times (Hb) \times Kh} = \frac{V\text{A} \times dF\text{A}(t)/dt}{\dot{Q}T \times (Hb) \times Kh}$$

By integration with respect to time, and application of the appropriate limits, this yields the following equation, given that when $t = 0$: $F\text{A} = F\text{A}, 0$, $Sa = Sa, 0$ and $dSa(t)/dt = 0$:

$$Sa(t) \times \Delta tc = Sa,0 \times \Delta tc - \frac{\dot{V}O_2 \times t}{\dot{Q}T \times (Hb) \times Kh} + \frac{V\text{A}(F\text{A},0 - F\text{A}(t))}{\dot{Q}T \times (Hb) \times Kh} - \frac{\Delta tc^2}{2!} \times \frac{dSa(t)}{dt}$$

Dividing throughout by Δtc, the term $\dot{Q}T$ (cardiac output) becomes QT (blood volume) and hence:

$$Sa(t) = Sa,0 - \frac{\dot{V}O_2 \times t}{QT \times (Hb) \times Kh} + \frac{V\text{A}(F\text{A},0 - F\text{A}(t))}{QT \times (Hb) \times Kh} - \frac{\Delta tc}{2!} \times \frac{dSa(t)}{dt} \qquad (8)$$

In common with equation (4), equation (8) is another differential equation, this time describing Sa in terms of $F\text{A}$, dSa/dt and t. Together these constitute a pair of simultaneous differential equations whose symbolic solution, although theoretically possible, is complicated. We therefore solved them iteratively by computer for real positive roots to yield values of Sa as t varies. An IBM compatible 486 PC was used using software written specifically for this purpose (this Microsoft Qbasic program is available from the authors on request).

A MANOEUVRE TO ACCOMMODATE THE EFFECT OF THE BOHR SHIFT DURING APNOEA

During the period of apnoea, as Pa_{O_2} decreases, so Pa_{CO_2} increases. This progressive hypercapnia produces a reduction in arterial pH. Both this reduction in arterial pH and the increase in Pa_{CO_2} independently affect the affinity of haemoglobin for oxygen.

Kelman's polynomial equation for the ODC [2] accommodates the Bohr shift by multiplying PO_2 (in mm Hg) by a correction factor to give a "virtual PO_2".

$$PO_2(\text{virtual}) = PO_2 \times 10^{[0.4\times(\text{pH}-7.4)+0.06\times(\log 40-\log PCO_2)]}$$

The F_{50} value for any given conditions of pH and FCO_2 (i.e. the "Bohr shift sensitive" value, dubbed F'_{50}) is therefore given by:

$$F'_{50} = \frac{F_{50,\text{standard}}}{10^{[0.4\times(\text{pH}-7.4)+0.06\times(\log 40-\log PCO_2)]}}$$

$$= \frac{F_{50,\text{standard}}}{\left(\frac{40}{[H^+]}\right)^{0.4} \times \left(\frac{0.0526}{FCO_2}\right)^{0.06}}$$

In acute respiratory acidosis, the resulting $[H^+]$ (nmol litre^{-1}) may be estimated from the following equation [3]:

$$[H^+] = 570(FCO_2) + 10$$

The F'_{50} value can therefore be calculated for any given FCO_2, and the greater the rate of increase of FCO_2 the more pronounced is the effect of the Bohr shift.

THE RATE OF INCREASE OF FCO_2 IN APNOEA

Carbon dioxide produced in the tissues is not deposited solely in the alveolar compartment but also in blood and other tissues. The great capacity for blood to combine with carbon dioxide buffers the rate of increase of Fa_{CO_2} such that abrupt changes in alveolar ventilation rate produce changes in Fa_{CO_2} which approach their steady-state values with half-lives of up to 14 min [4], where Fa_{CO_2} equals the fractional concentration of carbon dioxide with which arterial blood is in equilibrium.

The rate of increase of Fa_{CO_2} is given by:

$$\frac{dFa_{CO_2}}{dt} = \frac{\dot{V}CO_2}{V\text{A} + QT \times \frac{dCCO_2}{dF\text{A}_{CO_2}}}$$

where $\mathrm{d}C\mathrm{CO_2}/\mathrm{d}Fa_{\mathrm{CO_2}}$ = the slope of the carbon dioxide dissociation curve (carbon dioxide content in litres of carbon dioxide per litre of blood *vs* $Fa_{\mathrm{CO_2}}$). This slope is described by McHardy [5] and can be shown to be as follows:

$$\text{dissociation slope} = 178 \times m \times F\mathrm{CO_2}^{m-1}$$

$$\text{where} \qquad m = \frac{0.0448 \times (\mathrm{Hb}) + 6.3}{30}$$

In summary, therefore, given the haemoglobin concentration and initial $Fa_{\mathrm{CO_2}}$ value, the rate of increase of $Fa_{\mathrm{CO_2}}$ can be calculated. This allows calculation of $Fa_{\mathrm{CO_2}}$ and hence F'_{50} at any point in time. This latter value can be substituted into equation (4) to facilitate the computation of the time course of $Sa_{\mathrm{O_2}}$ incorporating the effects of the Bohr shift.

Results

The following conditions were applied in the model to produce a standard adult curve of $Sa_{\mathrm{O_2}}$ *vs* time (fig. 2, line B): (Hb) = 150 g litre^{-1}, cardiac output ($\dot{Q}\mathrm{T}$) = 5.0 litre min^{-1}, alveolar volume at resting expiratory level ($V\mathrm{A}$) = 2.5 litre, $\dot{V}\mathrm{O_2}$ = 0.25 litre min^{-1}, total blood volume ($Q\mathrm{T}$) = 5.0 litre, shunt fraction = 0, $F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}} = 0.133$, $Fa_{\mathrm{CO_2}\,\mathrm{initial}} = 0.0526$, $F_{50\,\mathrm{standard}} = 0.0359$.

The effect of the Bohr shift correction is also demonstrated in figure 2; line A is without any correction, and line B is corrected for the increasing $Fa_{\mathrm{CO_2}}$ throughout the apnoea. This correction is applied thereafter to all curves illustrating the model. Line C represents apnoea with an elevated initial $Fa_{\mathrm{CO_2}}$.

The effects of alterations in physiological variables on the rate of arterial oxyhaemoglobin desaturation are demonstrated in figure 3. The effect of different alveolar volumes is shown in figure 3A. The volumes shown represent alveolar volume at: total lung capacity (6.0 litre), resting expiratory level (2.5 litre) and supine resting expiratory level after anaesthesia (2.0 litre) [6]. The effects of $F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}}$ on the subsequent rate of oxyhaemoglobin desaturation is shown in figure 3B. These values were chosen to represent normality ($F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}} = 0.133$) and pre-apnoea hypoventilation ($F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}} = 0.1$). The effect of shunt is shown in figure 3C, the nominal values being 0%, 5%, 10% and 15% of $\dot{Q}\mathrm{T}$. The effect of variation in oxygen consumption rate (metabolic rate) is shown in figure 3D. The effect of alterations in the total oxygen carrying capacity of the blood is shown in figure 3E and F. This has been separated into the effects of anaemia (3E) and hypovolaemia (3F).

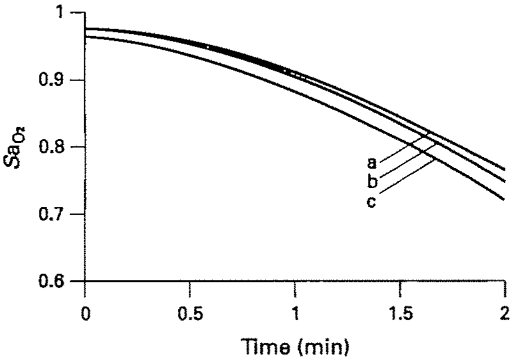

Figure 2 Effect of the Bohr shift on the time course of $Sa_{\mathrm{O_2}}$ in apnoea. a: ignoring the effect of the Bohr shift; b: implementing the dynamic Bohr shift within the same apnoea as above. This is the "standard adult" curve; c: implementing the dynamic Bohr shift during an apnoea with an elevated initial $F\mathrm{A}_{\mathrm{O_2}}$ (0.08).

SPECIFIC CLINICAL SCENARIOS

The model was used to predict the consequences of various clinical abnormalities on the time course of arterial oxyhaemoglobin desaturation during apnoea. The data for these examples are given in table 1.

Figure 4 shows theoretical plots for a standard adult, and 20-kg and 10-kg infants. A theoretical plot for a typical obese adult was constructed and is shown in figure 5. Figure 5 also shows the theoretical plot for a normal adult in the postoperative period after major surgery.

We have calculated the apnoea time required to reduce the oxyhaemoglobin saturation to 85% for a standard adult, a standard 10-kg infant and an obese adult both with and without preoxygenation (table 2). Preoxygenation, if resulting in complete nitrogen washout, is assumed to result in an $F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}}$ of 0.87 ($P\mathrm{B}$dry = 93.7 kPa, $P\mathrm{A}_{\mathrm{CO_2}}$ = 5.3 kPa and r = 0.8).

Discussion

We have described a model of oxyhaemoglobin desaturation in the apnoeic patient. All major variables in this model, namely $V\mathrm{A}$, $F\mathrm{A}_{\mathrm{O_2}\,\mathrm{initial}}$, $\dot{V}\mathrm{O_2}$, $Q\mathrm{T}$, shunt and total oxygen carrying capacity, may be expected to change in the perioperative period.

The alveolar volume at the onset of apnoea is an important determinant of the rate of oxyhaemoglobin desaturation because this is a large store of oxygen. As $F\mathrm{A}_{\mathrm{O_2}}$ is only 0.133 at an $F\mathrm{I}_{\mathrm{O_2}}$ of 0.21, changes in alveolar volume have a limited effect at this $F\mathrm{I}_{\mathrm{O_2}}$. The effect of reduced alveolar volume is more marked when $F\mathrm{A}_{\mathrm{O_2}}$ is higher, for example after preoxygenation (see below). The rate of oxyhaemoglobin desaturation was found to be very sensitive to changes in initial $F\mathrm{A}_{\mathrm{O_2}}$ with a reduction from 0.133 to 0.1, resulting in a shortening of the apnoea time required to reduce the oxyhaemoglobin saturation to 85% from 84 to 60 s. A reduction in initial $F\mathrm{A}_{\mathrm{O_2}}$ may occur with both hypoventilation and low mean $\dot{V}/\dot{Q}$, both of which increase $F\mathrm{I}_{\mathrm{O_2}} - F\mathrm{A}_{\mathrm{O_2}}$. Roe and Jones [9] have described low values of $Sp_{\mathrm{O_2}}$ (with $F\mathrm{I}_{\mathrm{O_2}} = 0.21$) in the postoperative period which returned to normal with an $F\mathrm{I}_{\mathrm{O_2}}$ value of 0.4. This would correspond to the behaviour predicted from their model [10] of the relationship between $F\mathrm{I}_{\mathrm{O_2}}$ and $Sa_{\mathrm{O_2}}$ in the presence of hypoventilation or low mean $\dot{V}/\dot{Q}$, suggesting that these patients may have had a low $F\mathrm{A}_{\mathrm{O_2}}$ value. It is of interest that these patients were also noted to have an unstable pattern of $Sp_{\mathrm{O_2}}$ at an $F\mathrm{I}_{\mathrm{O_2}}$ of 0.21. This is in accordance with the model described here where a low $F\mathrm{A}_{\mathrm{O_2}}$ value is associated with a greater propensity for oxyhaemoglobin desaturation.

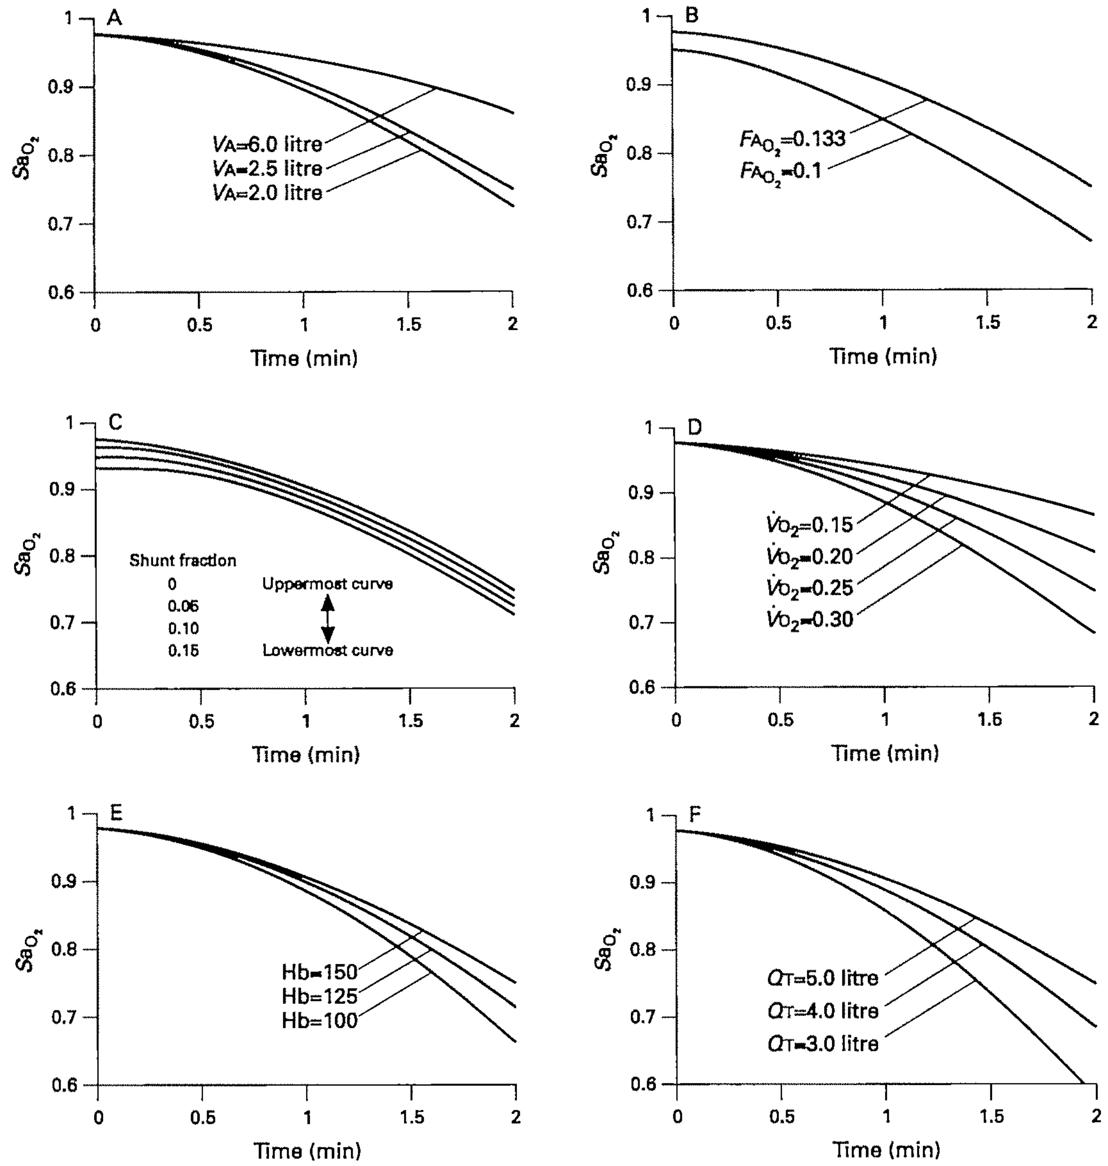

*Figure 3*A Effect of lung volume (*V*A litre) on the time course of Sa_{O_2} in apnoea. B: Effect of initial FA_{O_2} on the time course of Sa_{O_2} in apnoea. C: Effect of shunt fraction (f_s) ranging from 0 to 15% on the time course of Sa_{O_2} in apnoea. D: Effect of oxygen consumption rate ($\dot{V}O_2$) ranging from 0.15 to 0.3 litre min^{-1} on the time course of Sa_{O_2} in apnoea. E: Effect of haemoglobin concentration (Hb g $litre^{-1}$) on the time course of Sa_{O_2} in apnoea. F: Effect of total blood volume (*Q*T) on the time course of Sa_{O_2} in apnoea.

A spread of $\dot{V}/\dot{Q}$ mismatch (increased $\log_{SD} \dot{Q}$) has a complex effect involving a number of different compartments, contributing according to their size [10]. The effects of both reduced $FA_{O_2 initial}$ and reduced *V*A are combined in each compartment. The effect of spread of $\dot{V}/\dot{Q}$ ratios, as distinct from a reduction in mean $\dot{V}/\dot{Q}$, has not been modelled. However, the effect of mean $\dot{V}/\dot{Q}$ on $FA_{O_2 initial}$ is by far the most important effect of ventilation perfusion mismatch. A dispersion of $\dot{V}/\dot{Q}$ ratio about this mean results in some compartments (low $\dot{V}/\dot{Q}$) contributing to desaturation before others (high

Standard infant (10 kg)	41	180
Obese adult (127 kg)	46	171

$\dot{V}/\dot{Q}$), thereby to a certain extent cancelling each other out. An important exception is where there is a large contribution from an area of lung with very low $\dot{V}/\dot{Q}$. In this case the desaturation curve is determined, albeit in part, by the processes illustrated in figure 3B, resulting in a faster initial rate of desaturation. It is important to distinguish this effect from that of true shunt where the initial saturation but not rate of desaturation is altered (fig. 3C).

True shunt, measured by multiple inert gas elimination, increases during anaesthesia and this abnormality may persist for some time into the postoperative period. The effect of varying the shunt on the model is shown in figure 3C. It is evident from equation (4) that if a shunt exists, the arterial oxyhaemoglobin saturation is dependent on cardiac output. However, if the shunt fraction is zero, then arterial oxyhaemoglobin saturation is independent of cardiac output.

All physiological models have limitations. The model described here overcomes the serious deficiency of earlier models by taking account of the fact that apnoea is not a steady state situation. However, there are several assumptions that we have made in our model. We have assumed that alveolar gas is completely mixed at all times and is all immediately available for gas exchange. We have ignored the small change in lung volume which occurs when oxygen and carbon dioxide are exchanged with a respiratory quotient less than 1. We have assumed that cardiac output and $\dot{V}O_2$ remain unchanged during apnoea, although it is important to note that both of these variables may increase during the course of an obstructive apnoea. We assume that the circulation behaves as a single unit with a given mean transit time and with no mixing of blood. In the true situation, there is a spread of circulation transit time values as a result of the variation in blood circulation path lengths. In addition, mixing of blood occurs because of the distribution of velocities in laminar flow.

Oxygen consumption is commonly taken to be 0.25 litre min^{-1} although during anaesthesia a value in the region of 0.20 litre min^{-1} is more likely [11]. Delauney, Bonnet and Duvaldestin [12] studied $\dot{V}O_2$ in patients in the postoperative period and found values of approximately 0.15 litre min^{-1}, although this was increased by 40 % in patients who were shivering. Catabolic patients and patients with malignant hyperpyrexia have considerably increased $\dot{V}O_2$ values and desaturate at a much greater rate. Fletcher and colleagues [13] have shown an increased $\dot{V}O_2$ during obstructive apnoea. Increased metabolic rate associated with an increased $\dot{V}O_2$ value is also associated with increased $\dot{V}CO_2$. This alters the Bohr shift effect and has been incorporated in the construction of figure 3D (just as all plots are correct for Bohr shift) by assuming that $\dot{V}CO_2 = 0.8\ \dot{V}O_2$. A wide range of oxygen consumption is clearly possible and figure 3D shows the effect that this would have on the rate of oxyhaemoglobin desaturation.

The oxygen content of the blood, approximately 0.8 litre, might be expected to act as a "buffer" which moderates the rate of oxyhaemoglobin desaturation as oxygen is consumed from this compartment during apnoea. The total oxygen capacity of the blood is seen to be an important determinant of the rate of arterial oxyhaemoglobin desaturation in our model. This has been divided into consideration of the effects of anaemia (fig. 3E) and hypovolaemia (fig. 3F) because despite having common mechanisms within the model, they may be separate clinical entities. It should also be noted that fractional decrements in either have a multiplicative and not additive effect on the rate of arterial oxyhaemoglobin desaturation.

$S\bar{v}_{O_2}$ is not an independent variable determining the rate of desaturation but is linked through coupling with other variables. In the single apnoea, pre-apnoeic $S\bar{v}_{O_2}$ is lowered by either an increased oxygen consumption rate or a reduced cardiac output.

We have not incorporated into the model the effect of nitrous oxide elimination. Lampe and colleagues

[14] found that when nitrous oxide was added to isoflurane it failed to increase the incidence of early or late postoperative hypoxaemia compared with only oxygen and isoflurane. However, Einarsson and his co-workers [15] found reduced oxyhaemoglobin saturation after nitrous oxide anaesthesia in hypoventilating patients even when $F\text{I}_{O_2}$ was 0.3. As none of their desaturations was < 90%, diffusion hypoxia is probably an unimportant cause of postoperative hypoxaemia.

In both paediatric examples, an arterial oxyhaemoglobin saturation of 85% was reached after a considerably reduced apnoea time; 41 and 60 s, respectively, compared with 84 s in a standard adult. These reduced apnoea times were largely the result of a relatively high $\dot{V}O_2$ and a relatively low alveolar volume with respect to weight, compared with the standard adult (see table 1). In addition, despite the greater relative total blood volume, the "buffering capacity" of the blood oxygen store was reduced as a result of the low haemoglobin concentration.

In the example of a morbidly obese patient, an oxyhaemoglobin saturation of 85% was reached after 46 s (fig. 5). This was largely the result of a much decreased alveolar volume compared with a standard adult (see table 1). In addition, a lesser relative blood volume reduces the buffering capacity of the body oxygen stores.

The effect of preoxygenation on the time to Sa_{O_2} of 85% in a normal adult, a 10-kg infant and an obese adult (127 kg) is shown in table 2. Effective preoxygenation in a standard adult results in a time to Sa_{O_2} = 85% of 502 s. This is reduced to 180 s in the 10-kg infant and 171 s in the morbidly obese. This model result in the morbidly obese example is in agreement with the experimental data of Berthoud, Peacock and Reilly [16]. The reduced benefit of preoxygenation in the morbidly obese is a result of the very low alveolar volume which represents the only potentially increasable oxygen store in the body. The oxygen storage capacity of blood (as oxyhaemoglobin) has little capacity for any increase as a result of the shape of the oxyhaemoglobin dissociation curve.

The typical postoperative scenario (fig. 5) is to some extent a "worst case" example in that the effect of hypovolaemia, reduced cardiac output, anaemia, increased $\dot{V}/\dot{Q}$ mismatch, increased shunt, pre-apnoea hypoventilation and reduced alveolar volume are included. However, the values of these abnormalities individually are by no means excessive and each could easily occur in the postoperative period. It is important to appreciate that such abnormalities could occur in a variety of combinations and that some may be considerably more impaired than in this example. What is particularly interesting here is the marked rate of oxyhaemoglobin desaturation that occurs as a result of a combination of small abnormalities. The relative importance of abnormalities in these variables may be seen individually in figure 3. The initial oxyhaemoglobin saturation of 88.5% ($F\text{I}_{O_2}$ 0.21) is not uncommon in the early postoperative period. The short time (23 s) for this patient's oxyhaemoglobin saturation to reduce to 85% demonstrates the seriousness of apnoea in the postoperative patient where the initial oxyhaemoglobin saturation is reduced and the rate of oxyhaemoglobin desaturation from that level is increased. Here, relatively short periods of obstruction or apnoea lead to significant desaturations.

There has been some discussion as to whether or not oxyhaemoglobin desaturation is faster in obstructive rather than central apnoea. Strohl and Altose [17], however, found no difference in the rate of oxyhaemoglobin desaturation between simulated apnoea and obstruction in healthy subjects. Fletcher and co-workers [18], in an animal study, found a greater rate of oxyhaemoglobin desaturation during obstruction than during apnoea with paralysis. This difference was shown to be a result of increased $\dot{V}O_2$ in non-paralysed spontaneously ventilating but artificially obstructed animals. This increase in the rate of oxyhaemoglobin desaturation with increased $\dot{V}O_2$ is predicted by our model and is shown in figure 3D.

In summary, we have presented a model to describe the time course of oxyhaemoglobin desaturation during apnoea which illustrates the effect and interaction of various pathophysiological abnormalities which may occur. Insights gained from this model will be useful in understanding preoxygenation, postoperative hypoxaemia and sleep apnoea.

Appendix

A SIMPLE EXPRESSION FOR THE OXYHAEMOGLOBIN DISSOCIATION CURVE

End-capillary oxyhaemoglobin saturation can be expressed in terms of the alveolar oxygen fraction using this variation of the Hill equation [19, 20]. It is sufficiently accurate for the purposes of this model.

$$Sc' = b \times \left(\frac{F\text{A}_{O_2}{}^{n}}{F_{50}{}^{n} + F\text{A}_{O_2}{}^{n}} \right)$$

where $b = 0.998$, $n = 2.937$, $F_{50} = 0.0359$.

Nitrous oxide and the rate of gas uptake from an unventilated lung in dogs

C. J. JOYCE, A. B. BAKER, R. PARKINSON AND M. ZACHARIAS

Summary

We have studied the effect of $F_{I_{O_2}}$ of a nitrous oxide–oxygen mixture on the rate of gas uptake from an unventilated lung. Nine anaesthetized dogs were studied, each breathing four nitrous oxide–oxygen mixtures ($F_{I_{O_2}}$ 0.3, 0.5, 0.75 and 1.0) in random order. A double-lumen endobronchial tube separated lung ventilation. Both lungs were given the nitrous oxide–oxygen mixture for an equilibration period. Then the right lung was connected to a spirometer containing the same gas, and gas uptake measured. In every dog, gas uptake was faster with an $F_{I_{O_2}}$ of 0.5 or 0.75 than with an $F_{I_{O_2}}$ of 1.0. When breathing a nitrous oxide–oxygen mixture with $F_{I_{O_2}} > 0.3$, the rate of gas uptake from the unventilated lung was faster than with 100% oxygen. (*Br. J. Anaesth.* 1996; **76**: 292–296)

Key words

Anaesthetics gases, nitrous oxide. Lung, gas exchange. Oxygen, inspired concentration. Dog.

Pulmonary collapse is a common clinical problem after upper abdominal [1] and thoracic operations [2]. One of the proposed mechanisms of perioperative pulmonary collapse is absorption atelectasis [3]. Absorption atelectasis occurs when the net rate of gas transfer from the lung unit into the blood exceeds the rate of gas delivery into a lung unit by inspired ventilation. This may occur when gas is trapped behind closed airways and there is no ventilation to the corresponding lung unit [3, 4], although complete airway closure is not necessary [5, 6].

The rate of gas absorption from an unventilated area of lung depends on the inspired gas composition [7–10]. $F_{I_{O_2}}$ and the solubility of any inert gas in the inspired mixture are important determinants of the rate of gas absorption. If the inspired mixture contains a relatively insoluble gas such as nitrogen, the rate of gas uptake is relatively slow and increases as $F_{I_{O_2}}$ increases [9, 11]. When the inspired gas contains oxygen and a relatively soluble inert gas, gas uptake is faster. While nitrous oxide is less soluble than the volatile anaesthetic gases, in physiological terms nitrous oxide is highly soluble. Theoretical models predict that under some conditions an unventilated area of lung collapses more rapidly when breathing a nitrous oxide–oxygen mixture than when breathing 100% oxygen [9, 12].

Conditions that favour the development of absorption atelectasis exist during anaesthesia. Lung volume is reduced [13–22] and airways closure may occur [14, 23, 24], particularly in middle-aged or elderly patients [23]. Nitrous oxide–oxygen mixtures are commonly used as the inspired gas.

Dale and Rahn developed a dog preparation that measures the rate of gas uptake and the changes in gas composition within a lung, when ventilation to that lung ceases [8]. We used this preparation to examine gas uptake from an unventilated lung, when breathing nitrous oxide–oxygen mixtures with a range of $F_{I_{O_2}}$ values.

Materials and methods

Ethics approval for this study was obtained from the University of Otago Animal Ethics Committee. We studied nine healthy mongrel dogs (weights 18–39 kg). Anaesthesia was induced with i.v. thiopentone and maintained with a thiopentone infusion. After oral tracheal intubation, a femoral artery catheter and a Swan-Ganz pulmonary artery catheter were inserted. Spontaneous breathing was maintained throughout the experiment. Pulmonary arterial pressure, femoral arterial pressure and end-tidal carbon dioxide concentration were monitored continuously. Surgical tracheotomy was performed and a Rüsch double-lumen endobronchial tube for dogs inserted. The cuff of the endobronchial tube was inflated with 10 ml of water and the tube secured. Functional isolation of the lungs and patency of the endobronchial tube lumens were tested. When correct placement of the endobronchial tube was confirmed, breathing of the selected gas mixture began. A diagram of the breathing circuit and an explanation of its function are given in figure 1. In this preparation the right lung is not truly unventilated, but rather rebreathing from a small volume closed system with no fresh gas flow.

On each occasion both lungs breathed the test gas for at least 1 h to allow equilibration (tap A in "breathing circuit position"). End-tidal carbon dioxide was maintained at 5.3–8.6 kPa by adjusting the rate of thiopentone infusion. The spirometer was filled with the same test gas to a volume of 1000 ml

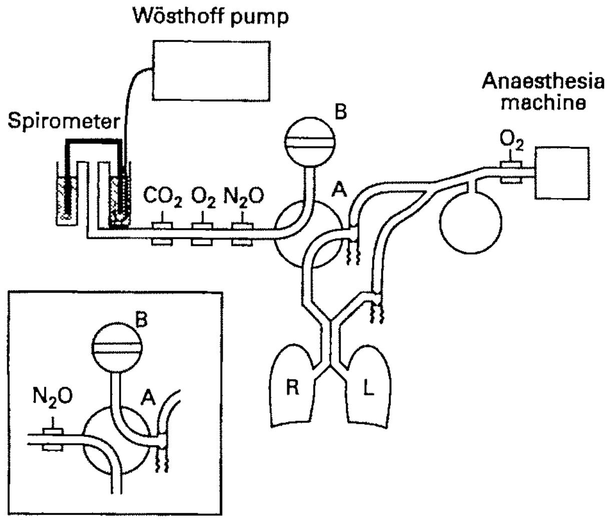

Figure 1 The breathing circuit. The main diagram shows the breathing circuit with tap A in the "breathing circuit position". Both lungs inhale from the reservoir bag, and exhale to atmosphere via one-way valves and reservoir tubing. Each lung ventilates through a separate non-rebreathing valve. The spirometer can be flushed out and filled with gas as desired, with tap B controlling whether the spirometer is open to atmosphere or sealed. When required for flushing or filling, gas of the desired composition was pumped into the spirometer from the Wösthoff pump via fine-bore tubing which was removed at the end of filling. "O_2", "CO_2" and "N_2O" are inline gas analysers. The insert shows the breathing circuit with tap A in the "spirometer position". The right lung is connected to the spirometer from which it rebreathes via the right endobronchial tube. The left lung continues to breathe gas from the reservoir bag as before.

above the bottom of its range. Recordings of arterial pressure, pulmonary artery pressure, spirometer volume and gas composition (partial pressures of oxygen, nitrous oxide and carbon dioxide) were started. At the end of an inspiration, tap A was turned to the "spirometer position", so that the right lung began to rebreathe from the spirometer, while the left lung continued to breathe test gas as before. Recordings were continued until the spirometer began to hit the stop at the bottom of its range. Just before this point was reached, mixed venous blood-gas samples were obtained. At the end of the recording, isolation of the lungs and patency of the lumens of the endobronchial tube were rechecked, then breathing of both lungs on the next test gas started.

All gas analysers in this experiment were "inline" and did not remove gas from the circuit. Instruments used were: oxygen analysis—Teledyne TED 100 polarographic oxygen analyser; nitrous oxide analysis—Dräger Irina anaesthetics measuring instrument analyser; and carbon dioxide analysis—Hewlett Packard 47210A CO_2 analyser with HP14360A carbon dioxide transducer. Blood gases were measured with a Radiometer ABL300 acid–base laboratory. A Krogh spirometer was used. The dead-space of the spirometer circuit including spirometer residual volume at the bottom stop, connecting tubing and the endobronchial tube, was 340 ml.

For each dog, recordings were made with four test gas mixtures. These were combinations of nitrous oxide and oxygen with F_{IO_2} values of 0.3, 0.5, 0.75 and 1.0, which were given in random order. When the recordings were analysed, observations of the pattern of composition and volume changes were made. The volume that 950 ml BTPS (37 °C, 760 Torr) would occupy at ambient temperature (ATPS) was calculated. The time for the spirometer volume at end-expiration to decrease by this amount (T_{950}) was measured: 950 ml BTPS was selected as the largest volume that could be measured from all the traces, before the spirometer began to hit the stop at the bottom of its range. P_{O_2} and the P_{CO_2} in the spirometer were recorded continuously, and noted at the time mixed venous P_{O_2} and P_{CO_2} were measured.

At the end of each study, after the nitrous oxide–oxygen recordings had been completed, eight of the dogs breathed 100% oxygen for at least 1 h, then recordings were made while the left lung continued to breathe 100% oxygen and the right lung rebreathed from the spirometer that had been filled with air (oxygen:air experiment). The rate of uptake from the spirometer when a state of constant composition within the spirometer had been reached and the uptake had stabilized was measured for F_{IO_2} 1.0 and the oxygen:air experiments. This allowed validation of the technique, by comparison with Dale and Rahn's results from a similar preparation [8]. This part of the experiment was not conducted on one of the nine dogs, because of time constraints on laboratory availability on the day that dog was studied.

The effect of F_{IO_2} on T_{950} was analysed using repeated measures analysis of variance. *Post hoc* testing was performed with both Fisher's PLSD (protected least significant difference) and Scheffé tests [25, 26]. These analyses were performed with Statview II version 1.04 using a Macintosh Centris 650.

Results

The results for T_{950} are presented in table 1 and figure 2. Repeated measures analysis of variance demonstrated a highly significant within-subjects difference between the results for the four gas compositions ($P = 0.0001$). Results of multiple comparison testing between the different gas com-

Table 2 Results of multiple comparison tests between T_{950} recorded with different $F\text{I}_{O_2}$ values

Comparison	Fisher PLSD	Scheffé
0.3–0.5	$0.001 < P < 0.01$	$0.01 < P < 0.05$
0.3–0.75	ns	ns
0.3–1.0	$0.01 < P < 0.05$	ns
0.5–0.75	ns	ns
0.5–1.0	$P < 0.001$	$P < 0.001$
0.75–1.0	$P < 0.001$	$0.001 < P < 0.01$

positions, with Fisher's PLSD and Scheffé tests, are presented in table 2. When $F\text{I}_{O_2}$ was greater than 0.3, the rate of gas uptake from the unventilated lung was faster than when $F\text{I}_{O_2}$ was 1.0.

The changes in gas composition in the spirometer depended on $F\text{I}_{O_2}$ (see fig. 3, table 3). With all $F\text{I}_{O_2}$ values, $P\text{CO}_2$ increased and stabilized slightly above $P\bar{v}_{CO_2}$. With an $F\text{I}_{O_2}$ of 0.3, $P\text{O}_2$ decreased to stabilize at a level slightly above $P\bar{v}_{O_2}$, and $P\text{N}_2\text{O}$ increased and stabilized. With an $F\text{I}_{O_2}$ of 0.5 or 0.75, $P\text{O}_2$ decreased linearly and $P\text{N}_2\text{O}$ increased linearly, with neither showing signs of stabilizing. With an $F\text{I}_{O_2}$ of 1.0, $P\text{O}_2$ decreased, then stabilized as $P\text{CO}_2$ stabilized. With $F\text{I}_{O_2}$ values of 0.5, 0.75 and 1.0, $P\text{O}_2$ in the spirometer was substantially higher than $P\bar{v}_{O_2}$.

Table 3 $P\bar{v}_{O_2}$ and $P\bar{v}_{CO_2}$ (kPa) measured just before the spirometer hit the bottom stop, and $P\text{O}_2$ and $P\text{CO}_2$ (kPa) in the spirometer at that time. Values are mean (SD) [range]

	$F\text{I}_{O_2}$			
	0.3	0.5	0.75	1.0
$P\bar{v}_{O_2}$	5.6 (1.2) [3.1–7.1]	7.6 (0.9) [6.0–8.8]	8.8 (1.1) [7.6–10.3]	9.1 (1.3) [7.3–11.9]
$P\text{O}_2$	8.0 (0.7) [6.9–9.1]	27.5 (1.9) [24.8–29.9]	55.7 (3.2) [49.7–60.0]	81.6 (3.5) [76.4–87.2]
$P\bar{v}_{CO_2}$	8.1 (1.3) [6.1–9.6]	8.9 (1.3) [6.8–10.9]	9.7 (1.2) [7.6–11.3]	9.5 (1.3) [7.3–11.7]
$P\text{CO}_2$	9.3 (1.3) [6.8–10.9]	10.4 (1.3) [8.5–11.7]	10.9 (1.1) [9.5–12.4]	11.1 (1.6) [8.5–13.7]

Table 4 Rate of uptake during constant composition in the $F\text{I}_{O_2}$ 1.0 and oxygen:air experiments (eight dogs). Presented as ml_{ATPS} min^{-1} kg^{-1} to allow comparison with Dale and Rahn's results (see discussion). Ratio of rate of uptake in $F\text{I}_{O_2}$ 1.0 experiment/rate of uptake in oxygen:air experiment, during constant composition, is also given

$F\text{I}_{O_2}$ 1.0	Oxygen:air	$F\text{I}_{O_2}$ 1.0/oxygen:air
5.64	0.644	8.76
4.90	0.370	13.23
2.49	0.554	4.50
4.35	0.643	6.77
3.28	0.280	11.70
3.25	0.187	17.38
3.23	0.314	10.29
3.12	0.493	6.33

A state of constant composition was reached during $F\text{I}_{O_2}$ 1.0 and the oxygen:air experiments. The ratio (rate of uptake during constant composition with $F\text{I}_{O_2}$ 1.0:rate of uptake during constant composition with oxygen:air) was calculated for individual dogs from our data (see table 4). These results (mean 9.87) were not significantly different ($P > 0.05$, one sample t test) from Dale and Rahn's mean value of 9.17 [8], supporting the validity of our experimental technique.

Discussion

When ventilation to a lung unit ceases, the rate of gas uptake from that lung unit by the blood determines the rate at which absorption atelectasis develops. We

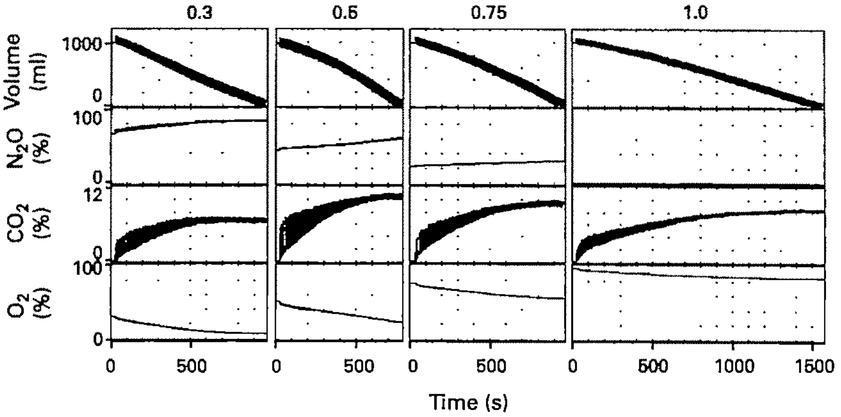

Figure 3 Volume and composition changes in the spirometer. Typical pattern of volume and composition changes in the spirometer. The recordings from one dog are shown for the four different $F\text{I}_{O_2}$ values.

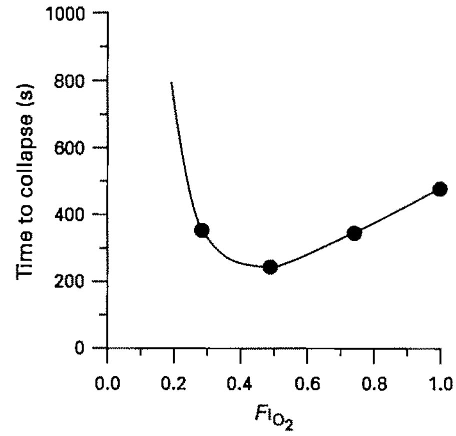

Figure 4 Predictions of mathematical model. A mathematical model [9] was used to predict time to collapse of a lung unit to which the airway becomes occluded while breathing different nitrous oxide–oxygen mixtures. Points on the line are predictions at the $F_{I_{O_2}}$ studied with the experimental preparation.

used a dog preparation to measure the rate of gas uptake and changes in gas composition within a lung, when ventilation to that lung ceased while breathing nitrous oxide–oxygen mixtures. It was found that the rate of gas uptake depended on $F_{I_{O_2}}$. When $F_{I_{O_2}}$ was greater than 0.3, the rate of gas uptake was faster than when $F_{I_{O_2}}$ was 1.0.

An area of non-ventilated lung, such as a lung or a pulmonary lobe with an occluded bronchus, or an alveolus with an occluded airway, behaves as a closed collapsible cavity with perfusion limitation [8, 9, 27, 28]. Most of the proposed methods of modelling gas uptake from closed collapsible cavities [29–31] have assumed that the oxygen and carbon dioxide in the cavity equilibrate instantaneously with venous blood. With our experimental preparation, P_{CO_2} in the spirometer approached $P\bar{v}_{CO_2}$ rapidly, but P_{O_2} in the spirometer did not always rapidly approach $P\bar{v}_{O_2}$ (see fig. 3, table 3). This demonstrates that when modelling gas uptake from an unventilated lung unit, it is reasonable to assume that equilibration is instantaneous for carbon dioxide, but this assumption is not valid for oxygen when breathing nitrous oxide–oxygen mixtures. This is in keeping with the prediction of mathematical models [9], that assuming instantaneous equilibration of oxygen introduces considerable inaccuracy. A mathematical model that made no such assumptions about equilibration rates [9] was used to calculate the time taken for an unventilated lung unit to collapse when breathing nitrous oxide–oxygen mixtures with a range of $F_{I_{O_2}}$ values. The results of these calculations are presented in figure 4. The absolute times depend on the initial volume of the lung unit and the blood flow to the lung unit, but the ratio (time to collapse with gas mixture A: time to collapse with gas mixture B) is independent of these factors. If this is taken into account there is a striking similarity in the pattern of results for T_{950} presented in figure 2, despite differences between the model and the experimental preparation.

P_{CO_2} in the spirometer initially increases because of mixing with alveolar gas, transfer of carbon dioxide from mixed venous blood into the spirometer and uptake of other gases concentrating carbon dioxide in the spirometer. As P_{CO_2} reaches the level of $P\bar{v}_{CO_2}$, transfer of carbon dioxide from mixed venous blood into the spirometer ceases, but uptake of other gases continues. P_{CO_2} in the spirometer continues to increase to an equilibration point slightly above $P\bar{v}_{CO_2}$, where the tendency of carbon dioxide in the spirometer to increase because of uptake of other gases is balanced by uptake of carbon dioxide from the spirometer into blood.

Webb and Nunn [12] calculated the changes in volume of a lung unit to which the airway became occluded while its blood flow remained constant at 11 % of total pulmonary blood flow. They found that if $F_{I_{O_2}}$ 1.0 was breathed at the time of occlusion, complete collapse of the lung unit took 10 min. If a nitrous oxide–oxygen mixture with an $F_{I_{O_2}}$ of 0.3 was breathed before and after the occlusion, collapse took 7 min. These results are in general agreement with our experimental findings. Unfortunately the article does not provide enough information to enable reproduction of their calculations.

Imagine that we could measure the volume and composition of gas within the lung after right main bronchus occlusion. Compare this with the experimental preparation. There are several important differences. First, with bronchial occlusion the lung volume forms the "closed collapsible cavity". In the experimental preparation it is formed by the combination of the volume added to the spirometer (1000 ml), the deadspace in the spirometer (181 ml) and the gas in the lumen of the double-lumen tube, the tubing leading to the spirometer and the gas analysers (162 ml), and lung volume (750 ml; estimated 30 ml kg^{-1} for 25-kg dog). Thus the volume of this cavity is approximately three times the lung volume. Uptake of gas would thus take three times as long to reach completion. There is no change, however, in the ratio (rate of uptake with gas mixture A: rate of uptake with gas mixture B) at a given fraction of the time taken for gas uptake to reach completion [9]. Second, in the experimental preparation the spirometer was filled with inspired gas that diluted the alveolar gas. Third, in the experimental preparation gas uptake could be studied only until the spirometer had emptied. We estimated 950 ml BTPS to be roughly half the volume of the cavity formed by the spirometer, tubing and lung volume. T_{950} is only valid as an index of gas uptake, if gas uptake is relatively constant over this volume. When nitrogen is included in the inspired gas mixture, T_{950} is not a valid index of gas uptake, as there is an initial period of rapid gas uptake followed by a slower rate of uptake when constant composition is reached [8, 9]. Theoretical analysis [9] and analysis of the volume recordings from this experiment demonstrate that when breathing nitrous oxide–oxygen mixtures the rate of uptake is relatively constant, allowing T_{950} to be used as a reasonable index of the rate of gas uptake. To compare rates of uptake with various nitrous oxide–oxygen mixtures, Dale and Rahn [8] measured the rate of uptake during constant composition. This could not be done when studying nitrous oxide–oxygen mixtures, because a state of constant composition is often not reached. Fourth, in the experimental preparation, there are mechanical effects of the circuit and spirometer on the lung that might delay gas mixing or produce alterations in blood flow to the right lung. Fifth, in the experimental preparation the lung is rebreathing from a closed system with zero fresh gas flow, so there are normal rhythmic ventilatory movements. Finally, atelectasis does not occur in the experimental preparation. Therefore, it does not measure atelectasis directly, instead it studies the process of gas exchange believed to underlie the development of absorption atelectasis.

This study showed that when a nitrous oxide–oxygen mixture with $FI_{O_2} > 0.3$ is breathed, the rate of gas uptake from an unventilated lung is faster than with 100% oxygen. This implies that these gas mixtures accelerate absorption atelectasis. It is not certain that absorption atelectasis is a significant factor in the genesis of perioperative collapse, and only clinical studies may inform us if avoiding certain gas mixtures reduces perioperative atelectasis. This study showed also that when nitrous oxide–oxygen mixtures are breathed, P_{O_2} within an area of non-ventilated lung does not always rapidly equilibrate with $P\bar{v}_{O_2}$. Models of gas uptake from an area of unventilated lung should not assume instantaneous equilibration of P_{O_2} with mixed venous blood.

Interpleural local anaesthesia: anatomical basis for mechanism of action

A. G. McKenzie and S. Mathe

Summary

India ink was injected through an extradural catheter placed in the right interpleural space in cadavers at autopsy. The lung was removed and the spread of the ink noted and photographed. In six cadavers, block sections were cut at the anterior axillary line through three ribs, intercostal muscles and parietal pleura. The blocks were fixed in formalin and then decalcified, sectioned, stained and mounted on slides. In all cases the ink covered the chest wall, lung and diaphragm, and was seen to pool in the paravertebral area. Examination of the histological slides revealed black pigment on the pleural surface and in the subpleural space. The mechanism of transport across the parietal pleura is discussed. (*Br. J. Anaesth.* 1996; **76**: 297–299)

Key words
Anaesthetic techniques, regional, interpleural.

Since the introduction of interpleural local analgesia in 1984 by Kvalheim and Reiestad [1], there have been numerous reports on the use and complications of the technique in the management of different types of pain [2]. However, there have been few investigations into the mechanism of action, which remains conjectural.

In the original abstract [1], Kvalheim and Reiestad suggested a mechanism of reverse diffusion of local anaesthetic through the parietal pleura into the subpleural space. From there, as shown in 1980 by Nunn and Slavin [3], the fluid could pass between the flimsy fascicles of the intercostalis intimus muscle to the intercostal space(s) and nerve(s). This mechanism seems to be supported by the observation of Miserocchi and colleagues [4], using gamma camera imaging, that a major distribution of fluid injected into the pleural cavity of anaesthetized dogs is in the paravertebral area, where the intercostal nerves are covered only by parietal pleura. Further support has come from studies on interpleural local anaesthetic in dogs, using somatosensory evoked potentials [5], and in patients using computed tomography [6].

The aim of this study was to investigate the spread of fluid injected into the pleural space of cadavers and, in particular, to determine if transport occurs through the parietal pleura.

Materials and methods

The study received ethics approval from the Medical Research Council of Zimbabwe. Criteria for the cadavers were that they were adult, scheduled for autopsy and without chest trauma or deformity. All cadavers had been refrigerated promptly and autopsy was performed within 48 h after death. Each cadaver was placed in the left lateral position and an extradural catheter inserted interpleurally through the right eighth intercostal space at the posterior axillary line. The interpleural space was located by the loss of resistance technique using a Tuohy needle and saline-filled syringe. The catheter was advanced 5–6 cm into the space between the parietal and visceral pleura, and the needle withdrawn. After successfully siting the catheter it was taped in position and the cadaver turned to the supine position. Then 20 ml of India ink was injected through the interpleural catheter and the cadaver left undisturbed for 30 min.

Following this, the chest was opened and the right lung removed carefully. The spread of ink within the thorax was noted and photographed. At the anterior axillary line, block sections were cut carefully through three ribs, intercostal muscles and parietal pleura. The specimens were fixed in 10% formalin before further histological preparation, which was performed in the following steps: (i) decalcification in formic acid–citric acid solution; (ii) routine processing and embedding in paraffin wax; (iii) cutting of 5 µm thick sections and staining with haematoxylin and eosin; and (iv) mounting on slides.

Results

No difficulties occurred during insertion of the interpleural catheters; interpleural injection of India ink was performed on seven cadavers. In one case, an empyema was found on opening the chest and this subject was withdrawn from the study (although the

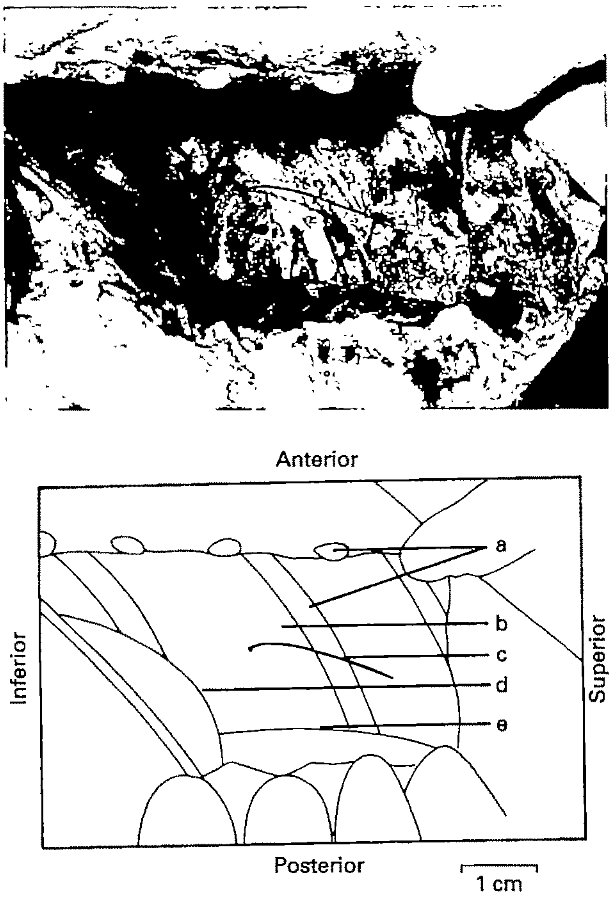

Figure 1 Top: distribution of India ink in the right hemithorax, 30 min after interpleural injection. The lung has been removed. The interpleural catheter is in the centre of the photograph. Bottom: line drawing for identification of structures above: a = rib, b = parietal pleura, c = catheter, d = diaphragm, e = paravertebral pooling of India ink.

spread of ink appeared to be wide). In each of the remaining six cases it was found that the catheter was well located in the interpleural space and the spread of ink was uniformly wide. The ink almost completely covered the chest wall, lung and diaphragm, tending to pool in the paravertebral area (fig. 1).

Examination of the histological slides prepared from all six specimens revealed normal bone, skeletal muscle and nerve tissue with black pigment on the pleural surface and in the subpleural space (figs 2, 3).

Discussion

Several studies have used cadavers injected with India ink to simulate intercostal nerve block [3, 7, 8]. Although the clinical relevance of India ink has been questioned [9], the differences between spread of India ink and local anaesthetic–indicator solution appear to have been quantitative rather than qualitative, as have differences between cadavers and patients. India ink is the most suitable dye when histological slides are required. It comprises a dispersion of carbon black in water; the suspension is stabilized with various agents. Carbon black is an extremely finely divided form of amorphous carbon. The particle size of the commercial grade used for India ink is 13–75 nm (0.013–0.075 μm) [10].

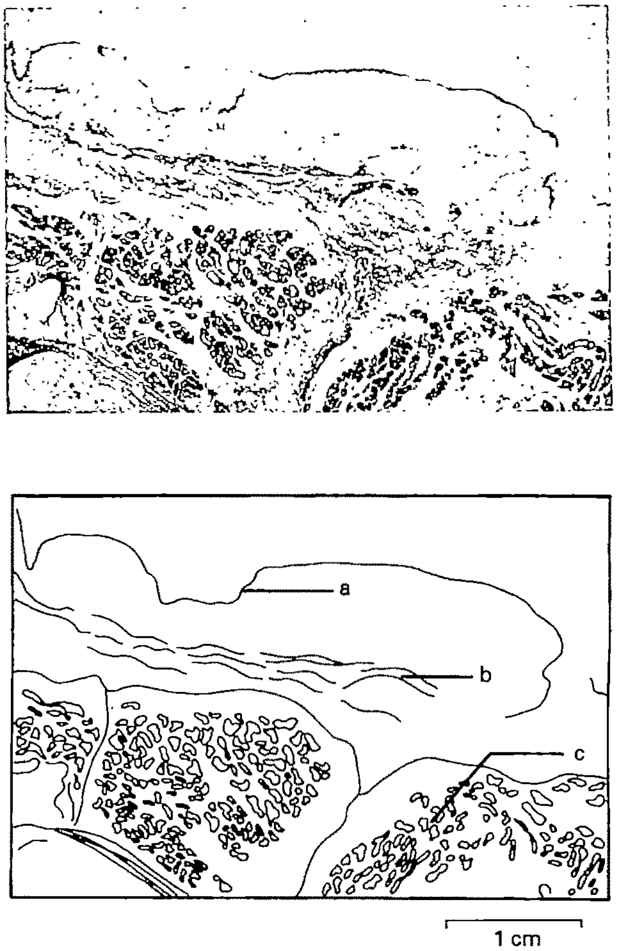

Figure 2 Top: photomicrograph of transverse section through the rib, intercostal muscle and parietal pleura after interpleural injection of India ink. Black pigment is visible on the pleural surface (×2.5 objective). Bottom: schematic diagram explaining the above: a = parietal pleura with black pigment on surface, b = black pigment in subpleural space, c = muscle cells.

The subpleural black pigment revealed in the histological slides was *not* regarded as formalin artefact, because it did not appear in bone in any of the slides. The pigment was also *not* considered to be melanin, because the subpleural tissue is too deep. We conclude that our results demonstrated movement of interpleural India ink (in cadavers) through the parietal pleura to the subpleural space.

Both parietal and visceral pleural surfaces are lubricated by a thin film of tissue fluid. Liquid injected into the pleural space is therefore added to tissue fluid. Two important differences have been observed between the parietal and visceral pleura [11]: (1) parietal pleura has stomata between the mesothelial cells (which form a single layer lining). These stomata are 2–12 μm in diameter; (2) the fibroelastic layer of the parietal pleura is much thinner, suggestive of a membrane compatible with fluid transport.

Diffusion in liquids is a slow process yet the onset of interpleural local anaesthesia is reported to be about 15 min. This suggests that the mechanism of transport across the parietal pleura may be more than diffusion, perhaps bulk flow. Transfer by macrophage activity may occur, but is excluded in this particular study, as cadavers were used.

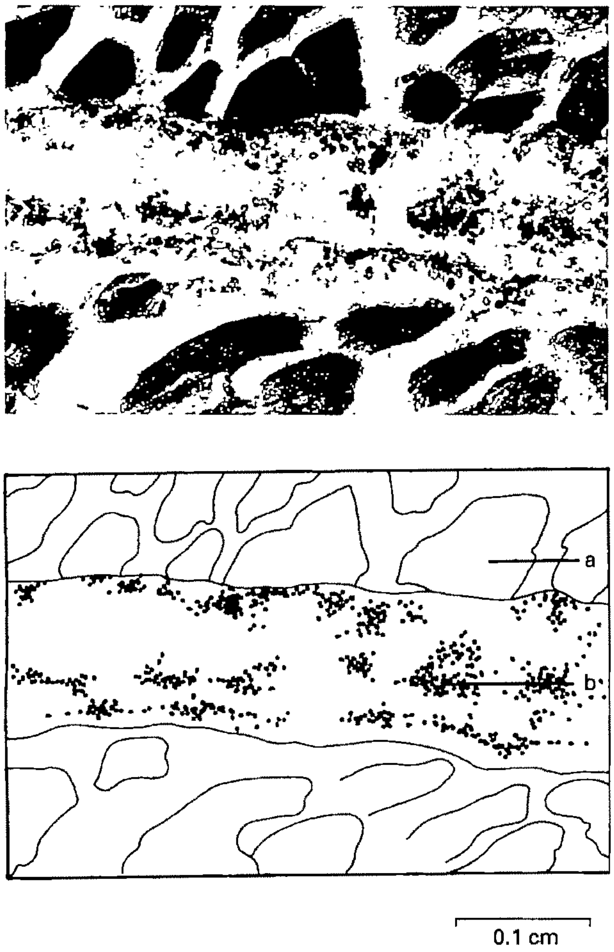

Figure 3 Top: photomicrograph of similar transverse section showing black pigment between muscle fibres (×25 objective). Bottom: schematic diagram explaining the above: a = muscle fibres (cut transversely), b = black pigment between muscle fibres.

Acknowledgements

We thank the Medical Research Council of Zimbabwe for permission to carry out this study and publish the findings. We also thank Dr J. H. McClure, Department of Anaesthetics, Royal Infirmary of Edinburgh, for helpful advice on the preparation of the manuscript.

REVIEW ARTICLE

Ropivacaine

J. H. McClure

Ropivacaine is a new aminoamide local anaesthetic. It is the monohydrate of the hydrochloride salt of 1-propyl-2′,6′-pipecoloxylidide and is prepared as the pure *S*-enantiomer. It is one of a group of local anaesthetic drugs, the pipecoloxylidides (fig. 1), which were first synthesized in 1957 [3]. Mepivacaine and bupivacaine are both well known members of this group and have been in clinical use for more than 30 years [4, 23, 82]. Mepivacaine has a methyl group, ropivacaine a propyl group and bupivacaine a butyl group on the piperidine nitrogen atom of the molecule.

The pipecoloxylidides are chiral drugs because the molecules possess an asymmetric carbon atom (fig. 1) and they may have a left-(sinister) or right-(rectus) handed configuration. Mepivacaine and bupivacaine are currently produced for clinical use as racemic mixtures of the enantiomers containing equal proportions of the "*S*" and "*R*" forms but ropivacaine is the single "*S*" enantiomer. It has an enantiomeric purity of 99.5 % and is prepared by the alkylation of the *S*-enantiomer of dibenzoyl-L-tartaric acid [25].

Differences in three-dimensional structure confer differences in the activity of enantiomers in the complex biological environment of the receptor [15]. This property of the pipecoloxylidides was known in the late 1960s because the different enantiomers had different durations of action at the target receptor in neural tissue [1, 47]. These differences in biological activity, whether measured in terms of desired or adverse effects, are not surprising because individual enantiomers bind to receptors or enzymes which are chiral amino acids with stereoselective properties. There may be differences in the activity of enantiomers of a drug: one may be active, the other partially active or inactive, or at the extreme, one may have an opposite effect to the other.

The clear advantages [22, 65, 72, 79, 80] of the long duration of action and sensory–motor differential block seen with bupivacaine consigned other members of this group of local anaesthetic drugs to the laboratory shelf, although some research work [2, 5] was carried out on the racemic mixture of the propyl homologue.

Historical background

In 1979, Albright published an alarming editorial [7] which associated the long-acting local anaesthetics, bupivacaine and etidocaine with cardiac arrest during regional anaesthesia. Albright reported six cases of presumed accidental intravascular injection of either bupivacaine or etidocaine which caused sudden ventricular arrhythmia occurring at the same time as severe convulsions. There were three cases of attempted brachial plexus block with 0.5 % bupivacaine, one i.v. regional anaesthetic with 0.5 % bupivacaine and chloroprocaine, one caudal extradural anaesthetic with etidocaine and, interestingly, only one case in this initial report was caused by 0.75 % bupivacaine used extradurally for Caesarean section. It was clear that there was a problem and there was a *paucity of experimental or clinical data delineating the effects of bupivacaine (and etidocaine) on the cardiovascular system above the convulsive threshold* at that time. Subsequently, sporadic cases of maternal death resulting from accidental i.v. injection of 0.75 % bupivacaine at the time of

extradural anaesthesia for Caesarean section were reported [48]. In the UK there were five deaths after i.v. regional anaesthesia performed by trainee casualty officers. Malfunction of an automatic tourniquet and the drug, bupivacaine, were common factors in these deaths [31]. Albright subsequently presented his findings to the United States Food and Drug Administration (FDA) which issued urgent recommendations about bupivacaine which contained the specific statement that 0.75 % bupivacaine was no longer recommended for obstetric anaesthesia. This sequence of events provided the impetus to develop a new local anaesthetic drug. It was possible that a drug of a lower lipid solubility compared with bupivacaine was less cardiotoxic.

The high lipid solubility of bupivacaine confers benefit by reducing absorption from the intended site of action, for example the extradural space. However, this property is not relevant if this site is bypassed when the drug is injected directly into the circulation. When a large dose of bupivacaine is injected rapidly into a vein, it is transported to the heart and brain and there is a high concentration of free drug available to cross the lipoprotein membrane of conducting tissue by first-pass extraction [74, 75]. After accidental i.v. injection, the mass of plasma protein (α_1-acid glycoprotein and albumin) in the volume of blood exposed to the drug is quickly saturated leaving a significant mass of unbound drug available for diffusion into conducting tissue of the heart and brain.

The FDA recommendations, while initially seeming illogical, in that it was the drug and not the concentration that was potentially cardiotoxic, achieved their objective. Appropriate measures, including slow or fractionated administration of a high dose of local anaesthetic drug, to detect potential systemic toxicity, have reduced the risk significantly.

Physiochemical properties

The physiochemical properties of lignocaine, ropivacaine and bupivacaine are summarized in table 1. The relative lipid solubility of ropivacaine, as measured by partitioning studies between N heptane and buffer and relative mean uptake into rat sciatic nerves, shows ropivacaine to be intermediate between lignocaine and bupivacaine. Plasma protein binding of ropivacaine is marginally less than that of bupivacaine but the pK_a is identical.

Preclinical studies

PRIMARY PHARMACODYNAMICS

Rosenberg and Heinonen in 1983 [63], using isolated sheathed vagus and phrenic nerves of rats, showed that ropivacaine at low concentration (25–50 µmol litre^{-1}) produced a profound and rapid block of both Aδ and C fibres and was more potent than similar low concentrations of bupivacaine in blocking these fibres. At higher concentrations, ropivacaine and bupivacaine had similar blocking activity. A study comparing higher doses of drug on isolated sheathed rabbit vagus nerve [11] found that A fibre block was 16 % greater with bupivacaine than similar concentrations (100, 150 and 200 µmol litre^{-1}) of ropivacaine. The degree of C fibre block was similar with both drugs at these concentrations.

Wildsmith and colleagues [83], using desheathed rabbit vagus nerves, found that ropivacaine blocked C fibres faster than A fibres and was a potent producer of frequency- (or use-) dependent block, that is block which only occurs when the fibre is stimulated. Low pK_a and high lipid solubility of a local anaesthetic drug favoured A over C fibre block whereas the reverse was true for high pK_a and low lipid solubility. Frequency-dependent block is considered to be related to lipid solubility and the molecular weight of the local anaesthetic drug. The lower lipid solubility of ropivacaine compared with bupivacaine is presumed to retard penetration of myelin sheaths.

This greater degree of differential block with ropivacaine at low concentration and the property of producing frequency-dependent block were considered to offer considerable clinical advantages in providing analgesia with minimal motor block.

Infiltration anaesthesia

Subcutaneous administration of ropivacaine 1 ml (0.25–0.5 %) has been shown to reduce cutaneous blood flow in pigs, as assessed by the laser Doppler method [43]. Bupivacaine in similar concentrations increased cutaneous blood flow. The addition of adrenaline 5 µg ml^{-1} to both ropivacaine and bupivacaine solutions reduced blood flow. Ropivacaine (0.25 ml of 0.25–0.75 %) has been shown to be two to three times longer acting than similar doses of bupivacaine when administered intradermally in the guinea pig [5]. The duration of effect of both drugs was increased further by the addition of adrenaline

Table 1 Physical properties of lignocaine, ropivacaine and bupivacaine. Data derived from Rosenberg, Kytta and Alila [64]

	Lignocaine	Ropivacaine	Bupivacaine

Partition coefficient (N heptane/buffer)	1	2.9	10
Mean uptake ratio (rat sciatic nerve)	1	1.8	3.3
Protein binding	65	94	95

5 μg ml^{-1}. An *in vitro* study on ring segments of the femoral artery and vein of dogs [54] confirmed that ropivacaine has a vasoconstrictive effect but this effect may be minimal with the doses used in clinical practice. No difference was found in skin blood flow or surgical bleeding when comparing 0.25% ropivacaine and bupivacaine given s.c. before skin incision in pigs [30]. However, the addition of adrenaline 5 μg ml^{-1} decreased blood flow by 50% when added to each drug.

Peripheral nerve block

Animal studies have shown that 0.5–1% ropivacaine consistently produces effective sensory and motor anaesthesia in sciatic nerve and brachial plexus block. Neither increasing the concentration above 0.75% nor adding adrenaline were found to significantly improve the duration of motor or sensory anaesthesia in peripheral nerve block. Onset time and duration of block were shorter with ropivacaine than equal concentrations of bupivacaine in the rat [28].

Central blocks

In extradural and spinal anaesthesia in the guinea pig, mouse and dog, ropivacaine and bupivacaine were found to be equipotent in terms of sensory block but the duration of motor block was shorter with ropivacaine [5, 28].

SECONDARY PHARMACODYNAMICS

In vivo *studies*

The toxic effects of local anaesthetics on the brain and heart provided the initial stimulus to develop ropivacaine and much of the early animal research involved assessment of the potential of this new drug to cause cardiotoxicity. Central nervous system (CNS) toxicity is related directly to the anaesthetic potency of local anaesthetic drugs and similar doses of ropivacaine and bupivacaine have been found to cause convulsions in conscious dogs [26, 27]. Early work showed little difference between the cardiotoxic effect of a bolus dose of ropivacaine or bupivacaine in sheep [66, 67] but at supraconvulsant doses in dogs [26] ropivacaine was less arrhythmogenic than bupivacaine. This reduced cardiotoxic potential with ropivacaine was confirmed subsequently in sheep and the ratio of fatal doses was 1:2:9 for bupivacaine:ropivacaine:lignocaine [55].

The effect of local anaesthetic on the electrophysiology of the heart has been defined further. The maximal rate of increase in the cardiac action potential (*V*max) is largely dependent on sodium ion influx via the sodium channels. All local anaesthetic drugs are known to depress *V*max in a dose-dependent manner depending on the membrane potential and rate of stimulation. Bupivacaine depresses *V*max considerably more than lignocaine and results in slowed conduction of the cardiac action potential which is manifest by prolongation of the PR and QRS intervals of the electrocardiograph [62]. This results in re-entrant phenomena and ventricular arrhythmia [37]. When bupivacaine is bound to cardiac muscle, recovery from block is slow. The sodium channels are blocked in a "fast-in, slow-out" manner which causes difficulty in resuscitation when ventricular fibrillation has occurred. Studies suggest that the cardiotoxicity of bupivacaine results from its high lipid solubility and that the "*R*" enantiomer is more toxic than the "*S*" enantiomer [77].

Ropivacaine is intermediate in its depressant effect on *V*max in guinea pig papillary muscle between bupivacaine (highest) and lignocaine (lowest) and recovery from block is slower with bupivacaine [8]. Moller and Covino, in two studies [50, 51], confirmed that ropivacaine was intermediate between bupivacaine and lignocaine in decreasing *V*max in isolated rabbit Purkinje fibres. Exogenous progesterone had no additional effect on depression of *V*max with ropivacaine in contrast with the effect of bupivacaine where depression of *V*max was increased [51]. This was considered to reflect the increased susceptibility to cardiotoxicity with bupivacaine seen in pregnancy.

A favourable cardiotoxic profile of ropivacaine compared with bupivacaine was confirmed in pigs [61]. An electrophysiological toxicity ratio, based on the inverse of the amount of local anaesthetic agent required to prolong the QRS interval to the same degree, was determined as 1:6.7:15 for lignocaine, ropivacaine and bupivacaine.

The cardiotoxicity of ropivacaine is not enhanced by pregnancy in sheep [68]. Early work [52] found that pregnancy enhanced the cardiotoxic effects of bupivacaine, but this has since been refuted [69]. Greater doses of ropivacaine (12.9 ± 0.8 mg kg^{-1}) compared with bupivacaine (8.5 ± 1.2 mg kg^{-1}) are required to produce circulatory collapse in pregnant ewes. Pregnancy did not appear to alter plasma protein binding by both drugs.

Bupivacaine has also been found to be more cardiotoxic than equivalent doses of lignocaine or ropivacaine in the isolated perfused rabbit heart (Langendorff preparation) [60]. Bupivacaine produced more severe arrhythmias than those observed with ropivacaine; lignocaine was devoid of arrhythmogenicity. The development of ECG disturbances and severe myocardial depression was more rapid with bupivacaine than ropivacaine.

Ropivacaine administered by i.v. infusion was found to be less toxic than bupivacaine in human volunteers. Mild CNS symptoms and minor cardiovascular toxicity, as measured by changes in conductivity and contractability, occurred at lower dosage and lower plasma concentration with bupivacaine compared with ropivacaine [70].

PHARMACOKINETICS

The pharmacokinetics of ropivacaine and bupivacaine after i.v. and extradural administration have been determined in the dog and Rhesus monkey [9, 40]. The effect of adrenaline on extradural administration has also been evaluated. The concentration of ropivacaine decreases more rapidly than bupivacaine during the elimination phase after i.v. infusion. Mean clearance (*Cl*) for ropivacaine in the dog was 41.1 ± 8.2 ml min^{-1} kg^{-1} compared with 32.3 ± 4.8 ml min^{-1} kg^{-1} for bupivacaine, although this difference was not statistically significant. After extradural administration the pharmacokinetic profiles of the two drugs were similar. Peak arterial ropivacaine concentration ($C_P$max) after extradural injection was higher for ropivacaine than bupivacaine with the 0.25 % concentration. The addition of adrenaline to either drug administered extradurally did not decrease $C_P$max consistently. The pharmacokinetic profiles of ropivacaine and bupivacaine in humans after extradural administration are similar to those determined in animal studies [38, 78].

The pharmacokinetic characteristics of ropivacaine after i.v. infusion have been determined in human volunteers [46]. Clearance (0.82 ± 0.16 litre min^{-1}) was found to be higher than the previously determined value for bupivacaine (0.58 litre min^{-1}). Plasma binding of ropivacaine averaged 94 ± 1 % (slightly lower than bupivacaine) and volume of distribution at steady state (V^{ss}) based on blood drug concentration was 59 ± 7 litre (cf. bupivacaine 73 litre). The terminal elimination half-life was 111 ± 62 min which is less than that determined previously for bupivacaine [75]. The higher clearance of ropivacaine compared with bupivacaine may offer an advantage in terms of systemic toxicity.

Human volunteer and clinical studies

The potency of ropivacaine in terms of sensory and motor block has now been determined in clinical use. A large number of open and double-blind studies have been performed on human volunteers and patients to determine the efficacy and degree of differential block with ropivacaine compared with bupivacaine in peripheral and central neural block.

Infiltration anaesthesia

Studies have been performed in human volunteers to determine the effect of ropivacaine compared with bupivacaine on cutaneous blood flow after intradermal injection of 0.1 ml of drug. Both bupivacaine and lignocaine produce vasodilatation in human skin, but a low concentration (0.25 %) of ropivacaine decreases skin blood flow [18]. Adrenaline 5 µg ml^{-1} reduces flow maximally when used alone but ropivacaine diminishes and does not accentuate the vasoconstrictive effect of adrenaline [19]. Plain solutions of ropivacaine produce a significantly longer duration of dermal analgesia than plain solutions of bupivacaine. Adrenaline significantly increases duration with both drugs [16]. The intradermal administration of small doses of local anaesthetic drug provides an interesting experimental model but this cutaneous vasoconstriction is observed with low doses and is not considered to be clinically important.

Ropivacaine (70 ml of 0.25 %) infiltrated into cholecystectomy wounds significantly decreases wound pain and increases the time to the first request for postoperative analgesia compared with saline [36]. However, wound infiltration with 0.25 % ropivacaine or bupivacaine 40 ml was equally effective in the management of post-herniorrhaphy pain [24]. There was no clinically significant difference between ropivacaine and bupivacaine in terms of duration of block or intensity of pain relief.

Peripheral nerve block

In a dose–response study in human volunteers undergoing bilateral ulnar nerve block, it was found that ropivacaine 2 ml was maximally effective at concentrations between 0.5 % and 0.75 % [58]. The profile of action resembled bupivacaine. The addition of adrenaline had no effect on onset time or duration of action of ropivacaine or bupivacaine. Several cases of residual paraesthesia lasting for longer than 1 month were observed with ropivacaine and bupivacaine. This was considered to result from needle trauma as there was no difference between ropivacaine and bupivacaine and there was no correlation with dose [58].

In a pharmacokinetic study bilateral intercostal block (T5–11) was performed in volunteers [44] using a total of 0.25 % plain ropivacaine or bupivacaine 56 ml. There was no difference in maximum plasma concentration ($C_P$max) but this tended to peak (tC_Pmax) earlier with ropivacaine. The terminal half-life $T_{\frac{1}{2}}^{\beta}$) was significantly shorter with ropivacaine. Sensory and motor block were of shorter duration with ropivacaine (6.0 ± 2.5 h) compared with bupivacaine (10.0 ± 3.0 h).

Brachial plexus block

Hickey and colleagues [32–35] studied ropivacaine in subclavian perivascular brachial plexus block. The addition of adrenaline to 0.5 % ropivacaine was not found to alter the pharmacokinetic properties of ropivacaine absorbed from the brachial plexus sheath. Ropivacaine 0.5 % was comparable with 0.5 % bupivacaine in terms of onset time and duration of effect, and motor block was profound with both drugs.

Lumbar extradural block

Open studies [20, 57, 81] of lumbar extradural administration of ropivacaine in concentrations of 0.5 %, 0.75 % and 1 % showed that ropivacaine was a long-acting local anaesthetic which gave surgical anaesthesia of good quality. Increasing the concentration decreased onset time and increased motor block, as occurs with other local anaesthetic agents [71]. The peak plasma concentration ($C_P$max) of ropivacaine was below the concentration associated with systemic toxicity in animals. Comparison of 0.5 % bupivacaine and ropivacaine showed that bupivacaine had a slightly longer duration of sensory and motor block but spread was similar [14]. Katz, Knarr and Bridenbaugh [39] compared 0.75 % ropivacaine 20 ml with 0.5 % bupivacaine 20 ml and no major differences were noted except that the time to two dermatome segment regression was of longer duration with 0.75% ropivacaine compared with 0.5% bupivacaine. Two studies [56, 85] comparing 1% ropivacaine and 0.75% bupivacaine found no difference in terms of onset, extent or duration of motor block but the duration of sensory block was longer and clinical efficacy was better with 1% ropivacaine compared with 0.75% bupivacaine. In elective hip surgery, 1% ropivacaine provided satisfactory anaesthesia more frequently than 0.5% bupivacaine and the duration of sensory and motor block was significantly longer [84]. The addition of adrenaline 5 μg ml^{-1} to 0.5% and 0.75% ropivacaine or bupivacaine did not appear to confer any advantage in terms of duration of action [17]. There were also no differences in block or cardiovascular effect other than those expected from extradural block itself [41, 42].

Brockway and colleagues [12] compared 0.5%, 0.75% and 1% ropivacaine 15 ml with 0.5% and 0.75% bupivacaine 15 ml in 110 patients and found no significant difference in onset, spread or duration of sensory block when similar concentrations were compared. However, ropivacaine produced a slower onset, shorter duration and less intense motor block than the same concentration of bupivacaine. Interestingly, four patients in this study, who were excluded from analysis of extradural block, received accidental i.v. injections which were not detected with a test dose of 1% lignocaine with adrenaline 3 ml. No patient, including one patient who received a total dose of 112.5 mg of ropivacaine, suffered from harmful systemic toxicity as a slow incremental injection of the main dose was given.

In a study of clinical efficacy and kinetics of the lumbar extradural administration of 10 ml of 1%, 20 ml of 0.5% ropivacaine and 20 ml of 0.5% bupivacaine, Morrison and colleagues [53] observed no difference between the groups in terms of onset, duration and spread of sensory block. Motor block produced by 0.5% ropivacaine was less intense and of shorter duration than that of 0.5% bupivacaine. The $C_P$max of ropivacaine was significantly greater and the terminal phase $T_{\frac{1}{2}}$ significantly shorter than that of bupivacaine.

Two volunteer studies of lumbar extradural block are considered pivotal in the interpretation of clinical data as they are the only studies which measured motor block in a quantitative manner. The modified Bromage scale [13] is simple to apply in a clinical setting and analyses movement in various muscle groups. It is a qualitative measure of spread and intensity of block. Mechanical measurement of the isometric muscle force (IMF) in a single muscle group is a more valid measurement of intensity of motor block [10, 45, 59, 87], although it is difficult to apply in the clinical situation and hence the importance of these volunteer studies.

In the first study [86] 0.5%, 0.75% or 1% ropivacaine 20 ml was given to 30 volunteers (10 in each group) in a bolus dose. Motor block was assessed by quantitative (IMF in separate muscle groups) and qualitative (modified Bromage scale) methods. Onset of motor block, as assessed by the quantitative method, was significantly slower with 0.5% ropivacaine and the intensity and duration of motor block increased with increasing dose. Motor block measured by the modified Bromage scale showed only the first part of the regression phase. Full recovery of muscle strength, as assessed by the qualitative method (Bromage scale = 0), was attained 1.5 to 2.5 h earlier than that assessed by the quantitative method.

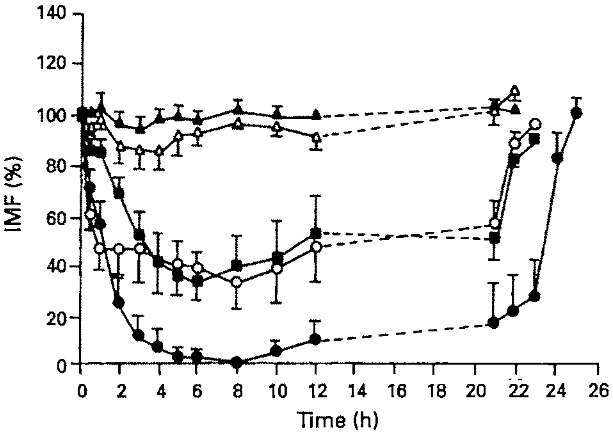

Figure 2 Motor block of the muscles of knee flexion in the 0.1% (△), 0.2% (■) and 0.3% (○) ropivacaine groups, and in the 0.25% bupivacaine (●) and saline (▲) groups (mean, SEM). IMF = Isometric muscle force. Reprinted with permission from Zaric and colleagues [88].

In the second study [88], volunteers (eight in each group) received a bolus dose of 0.1%, 0.2% or 0.3% ropivacaine 10 ml or 0.25% bupivacaine 10 ml followed by a continuous infusion of 10 ml h^{-1} of the same drug and concentration for 21 h. Similar sensory spread was seen in all groups. Bupivacaine 0.25% caused motor block of the greatest intensity as assessed quantitatively by IMF in three separate muscle groups. The regression phase of motor block when the infusion was stopped at 21 h was significantly shorter with all three concentrations of ropivacaine than with bupivacaine. This was seen most clearly in the knee flexors (fig. 2) but a similar profile was seen in the abdominal muscles and plantar flexors of the foot. This similar spread of sensory block, the reduced intensity of motor block and quick recovery observed with infusions of 0.2% and 0.3% ropivacaine compared with 0.25% bupivacaine offer distinct advantages in the clinical setting during extradural analgesia for labour or postoperative pain.

Spinal block

In a safety study, subarachnoid administration of 0.5% or 0.75% glucose free (plain) ropivacaine 3 ml were compared [76]. The incidence of complete motor block, as assessed by a qualitative method, was higher with 0.75% (18 of 20) compared with 0.5% (10 of 19) ropivacaine. The duration of analgesia was longer with 0.75% ropivacaine. No unexpected adverse events were registered, although there was a high incidence (11 of 40) of postdural puncture headache in this study of relatively young patients in whom a 26-gauge Quincke point needle was used.

The high proportion of patients not achieving complete motor block with 0.5 % ropivacaine 3 ml may have implications in terms of a "test dose" as the absence of full motor block may not exclude intrathecal placement of a catheter. Ropivacaine is not currently intended for use in spinal anaesthesia and research work has been restricted to safety analysis.

Extradural analgesia in labour

Two studies [49, 73] have been published, at the time of writing, comparing ropivacaine and bupivacaine in extradural analgesia in labour. The first study [49] compared a loading dose of 10 ml of 0.5 % followed by a top-up of 0.25 % ropivacaine or bupivacaine 10 ml. The other study [73] compared a continuous infusion of 0.25 % ropivacaine with 0.25 % bupivacaine 6–12 ml h^{-1} after a loading dose of 10 ml of this concentration. There was no difference in motor block in both studies, as assessed by the modified Bromage scale. This qualitative assessment may not be sensitive enough to detect differences in intensity of motor block in the segmental block required for analgesia in labour. Ropivacaine provided effective pain relief in labour and there was no difference in mode of delivery or neonatal outcome.

Extradural anaesthesia for Caesarean section

Ropivacaine 0.5 % has been compared with 0.5 % bupivacaine in extradural anaesthesia for Caesarean section. In one study [21] a standard dose of ropivacaine or bupivacaine 150 mg (30 ml) was given, and in another study [29] a mean volume of 23.7 ml of ropivacaine and 23.1 ml of bupivacaine was required to achieve an upper sensory level of block to the sixth thoracic dermatome. Both studies showed no difference in the profile of sensory block, but the duration of motor block with ropivacaine was significantly shorter compared with bupivacaine. Neonatal outcome and umbilical cord blood-gas tensions were similar. No detrimental effect has been observed with ropivacaine in extradural anaesthesia for Caesarean section on the uteroplacental or fetal circulations, as assessed by colour Doppler ultrasound [6].

Safety analysis

More than 2500 patients have now received ropivacaine in closely monitored controlled clinical trials evaluating the efficacy and safety of the drug. Details of all adverse events have been recorded and investigated. The reported incidences of serious adverse events that occurred in double-blind studies were lower during surgery, labour and Caesarean section with ropivacaine than with bupivacaine. None of the adverse events was considered to be drug related. Inadvertent i.v. injection of ropivacaine 75–200 mg occurred in five patients. None showed signs of cardiotoxicity. Convulsions occurred in one patient who received ropivacaine 200 mg intravascularly during an axillary brachial plexus block procedure. Prompt appropriate treatment led to full recovery within 2 min [personal communication, Dr Dag Selander].

Conclusions

Ropivacaine is an effective long-acting local anaesthetic and the first produced as a pure enantiomer. The sensory block provided by ropivacaine is similar to that produced by an equivalent dose of bupivacaine in extradural and peripheral nerve block. The motor block produced by ropivacaine is slower in onset, less intense and shorter in duration than that after an equivalent dose of bupivacaine. Motor block intensifies as the dose of ropivacaine is increased in extradural anaesthesia. This, together with its lower toxicity compared with bupivacaine, enables ropivacaine to be used for surgical anaesthesia in concentrations up to 1 %.

Ropivacaine is the first local anaesthetic drug to have been evaluated definitively, at an early stage in its development, as an analgesic for continuous extradural infusion. The profile of block with low doses of ropivacaine in terms of its greater sensory–motor separation and higher clearance than bupivacaine make it suitable for such use, although current experience is limited to 24 h. The clinical place of ropivacaine in extradural analgesia by continuous infusion during labour and the post-operative period has yet to be determined, but research to date suggests that ropivacaine offers distinct advantages over bupivacaine—the current local anaesthetic drug of choice.

SHORT COMMUNICATIONS

Dose of propofol for laryngeal mask airway insertion in children: effect of premedication with midazolam

R. A. MARTLEW, G. MEAKIN, R. WADSWORTH, A. SHARPLES AND R. D. BAKER

Summary

We determined the dose–response curves and effective doses of propofol for insertion of the laryngeal mask airway (LMA) in 50 unpremedicated children and in 60 children premedicated with midazolam, aged 3–12 yr. One of several doses of propofol was administered i.v. over 15 s to groups of 10 children, and conditions for LMA insertion were assessed at 60 s. The dose–response curves were parallel ($P = 0.94$), but the curve for premedicated children was shifted significantly to the left of that for unpremedicated children and propofol requirements were reduced by one-third ($P < 0.0001$). The doses required for satisfactory LMA insertion in 50% and 90% of unpremedicated patients (ED_{50}, ED_{90}) (95% confidence interval) were 3.8 (3.4–4.2) mg kg^{-1} and 5.4 (4.7–6.8) mg kg^{-1}, respectively; those for premedicated patients were 2.6 (2.2–2.8) mg kg^{-1} and 3.6 (3.2–4.3) mg kg^{-1}, respectively. (*Br. J. Anaesth.* 1996; **76**: 308–309)

Key words

Anaesthesia, paediatric. Anaesthetics i.v., propofol. Premedication, midazolam. Equipment, masks anaesthesia. Children.

Insertion of the laryngeal mask airway (LMA) soon after induction of anaesthesia is facilitated by the use of propofol, which depresses pharyngeal and laryngeal reflexes. The results of a previous study in children suggested that the dose of propofol required for insertion of the LMA may be greater than that for acceptance of a face mask [1]; however, there have been no formal studies to determine dose–response curves or effective doses. Oral midazolam is an effective sedative premedicant in children [2], which is synergistic with propofol [3] and may reduce the dose required for LMA insertion. Accordingly, the aims of this study were to determine the dose–response curves and effective doses of propofol for LMA insertion in unpremedicated and midazolam-premedicated children.

Methods and results

The study was approved by the Local Ethics Committee and written consent was obtained from the parents. We studied 110 children, ASA I or II, aged 3–12 yr and undergoing general anaesthesia for minor surgical procedures. Children with body weights outside the third to 97th centiles, and those with neuromuscular disease, anatomical abnormalities of the airway or asthma were excluded. Subjects were allocated randomly to one of two main groups to receive either no premedication ($n = 50$) or premedication with oral midazolam 0.5 mg kg^{-1}, 30–60 min before anaesthesia ($n = 60$).

Before induction of anaesthesia, a pulse oximeter and ECG monitor were attached and children were allocated randomly to subgroups of 10, to receive one of several predetermined doses of propofol: five groups of unpremedicated patients received 3.0, 3.4, 3.9, 4.4 or 5.0 mg kg^{-1}, while six groups of premedicated patients received 2.2, 2.6, 3.0, 3.4, 3.9 or 4.4 mg kg^{-1}. To reduce pain on injection, lignocaine 10 mg was added to each 100 mg of propofol. Propofol was administered over 15 s via an i.v. cannula sited on the back of one hand, following which the lungs were ventilated with 100% oxygen for 60 s before attempting insertion of the LMA as described in the manufacturer's instructions [4]. Conditions for LMA insertion were assessed by an anaesthetist who was unaware of the dose of propofol and the type of premedication given. Conditions were considered satisfactory if the jaw was relaxed, there was no coughing, gagging, swallowing or laryngeal spasm, and minimal or no limb movement. If conditions were considered to be unsatisfactory, anaesthesia was deepened with further increments of propofol, or an inhalation agent, or both, until the LMA was tolerated. Oscillometric arterial pressure measurement was commenced after insertion of the LMA and continued at 3-min intervals throughout surgery.

Dose–response data were analysed by probit analysis. Maximum likelihood estimates of model variables were found using a Fortran program written by one of the authors (R.D.B.); numerical algorithms group (NAG) routines were used for functional minimization. The slopes and intercepts

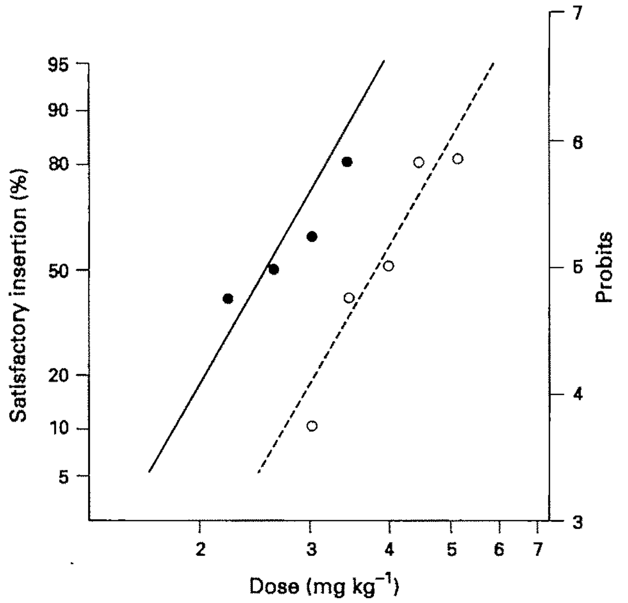

Figure 1 Log dose–probit response curves of propofol for LMA insertion in unpremedicated (○) and midazolam-premedicated (●) children. The points along the lines represent mean responses from subgroups of 10 patients. Only four of the six points can be shown for the midazolam group, as satisfactory LMA insertion conditions were obtained in 100% of patients who received the two higher doses (probit = ∞).

of the dose–response lines for unpremedicated and premedicated patients were compared using analysis of deviance, and 95% confidence intervals on ED values were found using the profile likelihood function [5]. Statistical differences in patient data were assessed by one-way ANOVA.

There were no significant differences in mean ages and weights of the children in the various propofol dose groups, or in the times from administration of midazolam to induction of anaesthesia in the groups of premedicated children. Log dose–probit response curves for unpremedicated and midazolam-premedicated children are shown in figure 1. The equations of the lines were probit = 3.8 log dose −0.09 and probit = 3.8 log dose −3.7, respectively. The slopes of the lines did not differ significantly ($P = 0.94$), but the curve for premedicated children was significantly to the left of that for unpremedicated children ($P < 0.0001$).

The effective doses of propofol for LMA insertion in 50% and 90% of unpremedicated children (ED_{50}, ED_{90}) (95% confidence intervals) were 3.8 (3.4–4.2) mg kg^{-1} and 5.4 (4.7–6.8) mg kg^{-1}, respectively; those for premedicated children were 2.6 (2.2–2.8) mg kg^{-1} and 3.6 (3.2–4.3) mg kg^{-1}, respectively. The differences in effective doses between unpremedicated and midazolam-premedicated children were highly significant ($P < 0.001$).

Comment

The results of the present study confirm that induction of anaesthesia with propofol allowed early insertion of the LMA in paediatric practice. The effective dose of propofol for insertion of the LMA in 90% of unpremedicated children exceeded 5 mg kg^{-1}, but this was reduced to less than 4 mg kg^{-1} after premedication with midazolam. our results support the suggestion that the dose of propofol required for insertion of the LMA is greater than that required for acceptance of a face mask in children [1] and may be proportionally greater than that required for LMA insertion in adults [6, 7]. Increased induction requirements for propofol in children may be explained by a larger central volume of distribution of the drug [8, 9] and a greater cardiac output per kilogram body weight, which should result in a lower peak concentration of propofol in the blood perfusing the brain after bolus injection.

The ED_{90} propofol dose of more than 5.0 mg kg^{-1} in unpremedicated children exceeds previous recommendations for induction of anaesthesia. As propofol is known to produce cardiorespiratory depression in children at doses considerably less than this [10], hypotension or prolonged apnoea may be a problem. However, during the study we did not observe any differences in the incidence of cardiorespiratory side effects between the low and high dose propofol groups.

Comparison of i.v. and s.c. diamorphine infusions for the treatment of acute pain in children

D. SEMPLE, L. A. ALDRIDGE AND E. DOYLE

Summary

We have compared the i.v. and s.c. routes of administration for diamorphine infusions in children undergoing abdominal surgery. Subjects received general anaesthesia with extradural block and diamorphine up to 20 μg kg^{-1} h^{-1} after operation. There were no differences between the groups in diamorphine consumption, pain scores or incidence of side effects. The s.c. route appeared to be as effective and safe as the i.v. route for administration of diamorphine infusions in children undergoing elective surgery. (*Br. J. Anaesth.* 1996; **76**: 310–312)

Key words

Analgesia, paediatric. Analgesic techniques, i.v. Analgesic techniques, s.c. Analgesics opioid, diamorphine. Pain, postoperative.

The use of i.v. opioid infusions to treat postoperative pain in children is a common and effective analgesic technique [1]. It requires a dedicated i.v. cannula for opioid administration in addition to one for i.v. fluids and drugs. Alternatively, the same cannula may be used for both fluids and opioid administration if an antireflux valve is used. The option of a second i.v. cannula is not always available, particulary in infants, while antireflux valves are expensive and make the infusion site bulky and difficult to nurse.

An alternative route of administration for opioid infusions which does not have these disadvantages is the s.c. route. This is used extensively in terminal and chronic pain and has also been described for the management of acute pain in adults [2]. The efficacy of s.c. infusions in children has been demonstrated recently [3]. For this technique to become widespread and accepted it must be shown to be as effective as the i.v. route with the same or a lower incidence of side effects. The i.v. and s.c. routes of administration have not been compared in children. This study was designed to compare these two routes in children undergoing abdominal surgery. On the basis of previous work using similar methodology [4] the power calculated for the study was that it would have a 90 % chance of detecting differences between the groups which were significant at the 5 % level.

Methods and results

The study was approved by the local Ethics Committee and written informed parental consent was obtained for each subject. We studied 30 children, aged 6 months to 11 yr, undergoing abdominal surgery. Exclusion criteria included contraindications to extradural block, significant hepatic or renal impairment, and significant mental handicap making assessment of pain difficult. Patients were premedicated with EMLA cream and anaesthesia was induced with propofol 3–4 mg kg^{-1} and atracurium 0.5 mg kg^{-1}. After tracheal intubation, the lungs were ventilated with 0.5–2 % halothane and 70 % nitrous oxide in oxygen. Patients were then turned to the right lateral position and an extradural catheter placed at an appropriate dermatomal level for the proposed surgery. Extradural block was provided with 0.25 % bupivacaine 1 ml kg^{-1} with adrenaline 1/200000 (maximum 20 ml) in divided doses. At the end of surgery, neuromuscular block was antagonized and the trachea extubated.

Patients were allocated randomly to receive either an i.v. or an s.c. infusion of diamorphine after operation. In the i.v. group (group IV), a second 22-gauge cannula was sited on the same side as the cannula used for induction. In the s.c. group (group SC), a 22-gauge cannula was sited s.c. over the deltoid muscle on the same side as the i.v. cannula.

In group IV the solution used consisted of diamorphine 1 mg kg^{-1} diluted in 50 ml of 0.9 % saline to give a concentration of 20 μg kg^{-1} ml^{-1}. This was commenced at a rate of 1 ml h^{-1} (20 μg kg^{-1} h^{-1}). In group SC the solution used consisted of diamorphine 1 mg kg^{-1} diluted in 20 ml of 0.9 % saline to give a concentration of 50 μg kg^{-1} ml^{-1}. This was commenced at 0.4 ml h^{-1} (20 μg kg^{-1} h^{-1}). Diamorphine infusions were started in the recovery area. Infusions were delivered using a Graseby MS2000 pump.

After operation we used a monitoring regimen described previously [5]. Patients breathed air and had continuous monitoring of arterial oxygen saturation. We measured hourly values of ventilatory frequency, pain score, sedation score, nausea score and volume of diamorphine infused. Diamorphine was infused at a maximum rate of 20 μg kg^{-1} h^{-1} and boluses of diamorphine 50 μg kg^{-1} were available if required.

Pain was assessed by a small group of experienced paediatric surgical nurses and measured using a

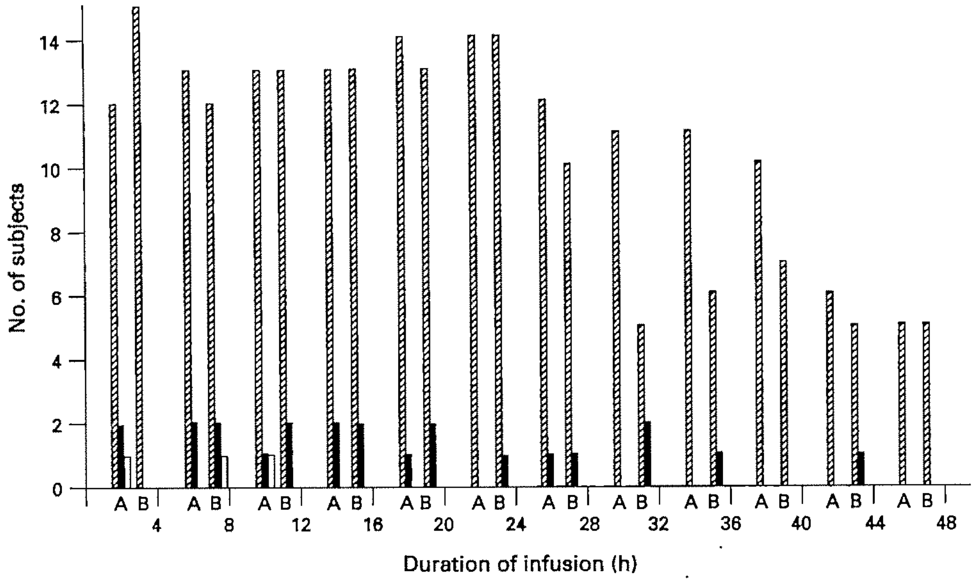

Figure 1 Comparison of pain scores (▨ = 1, ■ = 2, □ = 3) in groups IV (A) and SC (B).

four-point scale described previously [6]: 1 = no pain; 2 = mild pain; 3 = moderate pain; 4 = severe pain. Children were not wakened from sleep for assessments unless the nurse suspected excessive sedation. Sedation was scored using a four-point scale: 0 = eyes open spontaneously; 1 = eyes open in response to speech; 2 = eyes open when shaken; 3 = unrousable. Vomiting was scored on a three-point scale: 0 = none; 1 = vomited once in the last hour; 2 = vomited more than once in the last hour.

Infusions were discontinued when there was a consistent decline in diamorphine requirements and patients were able to take oral analgesics. Results were analysed using the Student's *t* test for parametric data and the Mann–Whitney *U* test for non-parametric data.

The two groups were similar in characteristics (mean age 36 months in group IV and 33 months in group SC), surgical procedures (eight gastrointestinal, two pyeloplasties, three nephrectomies and two ureteric reimplantations in group IV and six gastrointestinal, two pyeloplasties, five nephrectomies and two ureteric reimplantations in group SC) and duration of surgery (median 80 min in group IV and 65 min in group SC).

The duration of infusion analgesia (median 41 h in group IV and 39 h in group SC) and total diamorphine consumption (median 680 (range 220–1120) $\mu g\,kg^{-1}$ in group IV and 600 (260–1160) $\mu g\,kg^{-1}$ in group SC) did not differ significantly between the groups. To assess efficacy, we compared the median total pain scores in each group during each 4-h period after operation. There were no significant differences between the groups at any point (fig. 1). Two children in group IV and three children in group SC received one supplementary bolus of diamorphine for inadequate analgesia at the maximum infusion rate.

There were no significant differences between the groups in the incidence of vomiting, excessive sedation or hypoxic episodes. Five patients in group IV and seven patients in group SC vomited. Excessive sedation was defined as a sedation score of 2 or 3; a score of 2 occurred on two occasions in one patient in group IV and on seven occasions in two patients in group SC. All episodes of excessive sedation occurred during the first postoperative day while the infusion rate was 20 $\mu g\,kg^{-1}\,h^{-1}$. A hypoxic episode was defined as Sp_{O_2} less than 94%; there were 14 episodes in four patients in group IV and 18 episodes in five patients in group SC.

Two cannulae in group IV and no cannulae in group SC needed to be replaced during the diamorphine infusion.

Comment

We have observed that the s.c. route of administration is as effective as the i.v. route for infusion of diamorphine in children after elective surgery. Although s.c. administration has been shown to provide analgesia [3] in children, it has not been shown previously to be as effective as the i.v. route.

The fact that equivalent analgesia can be provided by this route with similar doses of diamorphine and no increase in the incidence of side effects suggests that this technique may be useful in children receiving other opioids by infusion. Use of the s.c. route for opioid infusions is likely to reduce the practical difficulties associated with the provision of this form of analgesia in small children. Intermittent injections of opioid through an indwelling s.c. cannula may be used instead of an infusion but, in common with intermittent i.m. injections, may result in periods of unrelieved pain alternating with episodes of sedation or nausea induced by high plasma concentrations of opioid after bolus dose administration. There was no blinding of observers to the type of infusion used in this study and there is the possibility of bias in the recordings. Furthermore the method of pain assessment used (observer scoring) is not as satisfactory as patient self-report and must be considered to be a relatively insensitive discriminator between analgesic regimens.

It should be noted that the subjects in this study were elective normovolaemic patients. The s.c. route would be contraindicated in patients with or at risk of developing poor peripheral perfusion when there would be a risk of accumulation of opioid at the infusion site resulting in poor analgesia and subsequent absorption of this depot to give the equivalent of a large uncontrolled bolus of opioid.

Prospective evaluation of pharmacokinetic model-controlled infusion of propofol in adult patients

T. G. SHORT, T. A. LIM AND Y. H. TAM

Summary

We have tested prospectively the algorithm of White and Kenny for pharmacokinetic model-controlled infusion of propofol in 40 healthy Oriental adults. Anaesthesia consisted of a target-controlled infusion of propofol, 70% nitrous oxide and an infusion of alfentanil. For the first 20 patients studied, median performance error was −5%, median absolute performance error 19%, divergence −9% and wobble 6%. The model was revised to minimize the prediction error of the variable set and tested prospectively in another 20 patients. There was a deterioration in performance of the revised model. Performance statistics for the original model in all 40 patients were: median performance error 2% (range −34 to 69%), median absolute performance error 21% (6–69%), divergence −17% (−92 to 49%) and wobble 7% (2–34%). The algorithm was found to perform adequately in our Oriental patient population. (*Br. J. Anaesth.* 1996; **76**: 313–315)

Key words

Anaesthetic techniques, i.v. Drug delivery, computerized. Anaesthetics i.v., propofol, Pharmacokinetics, models.

Successful use of pharmacokinetic model-controlled infusions of drugs in anaesthetic practice requires the use of thoroughly tested algorithms. A recent study of pharmacokinetic model-controlled infusion of propofol in Oriental paediatric patients performed at our institution found this patient group to be described by different pharmacokinetic variables from paediatric patients in a previous study performed by Marsh and colleagues [1, 2]. Their model underestimated propofol requirements in our paediatric patient population by 18%. Because of this pharmacokinetic difference, we decided that the accuracy of a similar algorithm for the infusion of propofol in adult patients should also be tested prospectively in our adult population [3].

Methods and results

We studied 40 ASA I or II adult patients, aged 20–60 yr, undergoing elective surgery expected to last at least 1 h and associated with minimal blood loss. Patients with a preoperative haemoglobin concentration of less than 11 g dl^{-1}, more than 50% above ideal weight or with a contraindication to the use of propofol were excluded. The study was approved by the local Ethics Committee and written informed consent was obtained from all patients.

Patients were premedicated with temazepam 20 mg. Anaesthesia consisted of a pharmacokinetic model-controlled infusion of propofol programmed to rapidly achieve and then maintain a constant concentration in the central compartment. The drug delivery system consisted of an Ohmeda 9000 syringe pump (Medishield, UK) controlled by an IBM compatible computer, as described previously [1]. Rate constants for the three-compartment pharmacokinetic model used were White and Kenny's adaptation of the pharmacokinetic variables of Gepts and colleagues: V_1 (litre kg^{-1}) 0.2280, k_{10} (min^{-1}) 0.1190, k_{12} 0.1120, k_{21} 0.0550, k_{13} 0.0419 and k_{31} 0.0033 [2–4]. The initial target blood concentration was set at 6.0 μg ml^{-1} and then adjusted according to clinical response. Patients also received alfentanil 7 μg kg^{-1} at induction followed by an infusion of 0.25 μg kg^{-1} min^{-1}, 70% nitrous oxide and atracurium if required. The anaesthetic technique was similar to that used by White and Kenny when they prospectively tested this algorithm [4].

After induction of anaesthesia a 22-gauge cannula was placed in a radial artery for blood sampling. At 5–10-min intervals throughout the procedure and at 15–20-min intervals during the first 2 h after cessation of the infusion, 2.0-ml blood samples were obtained. No blood samples were obtained during stepwise increases in propofol concentration. Blood samples were stored and analysed as described previously [1]. Accuracy of the assay was 6.7% at 50 ng ml^{-1} and 4.0% at 3000 ng ml^{-1}.

Performance of the computer-controlled infusion system was assessed using a variance weighted two-stage approach [5]. Performance error was calculated as: performance error $= ((C_{\mathrm{Pmeasured}} - C_{\mathrm{Ppredicted}})/C_{\mathrm{Ppredicted}}) \times 100$, where C_{P} = whole blood concentration of propofol. For each individual, median performance error (MDPE), median absolute per-

formance error (MDAPE), divergence and wobble were then calculated. Overall performance of the system in the sample population was then assessed as the variance weighted mean of MDPE, MDAPE, divergence and wobble calculated for each individual. Data from the first 20 patients were used to develop an optimized pharmacokinetic variable set with theoretically superior performance when used in our system with a linear least squares regression procedure to find the variable set that would best fit the data by minimizing performance error. The median performance of the revised model for each patient was compared with the median precision of the original model using Wilcoxon's signed rank test. Because the revised variable set was found to fit the data better than the original model for most measures of performance, the revised variable set was then tested prospectively in another 20 patients.

Mean age of the patients was 37 (range 21–58) yr and weight 58 (41–74) kg; 75 % of patients were female and 75 % underwent ventilation of the lungs. Mean duration of propofol infusion was 90 (34–190) min. There were no significant differences in age, weight or sex of patients in the two phases of the study. Operations performed included gynaecological, orthopaedic and general surgery. Blood concentrations required for adequate anaesthesia ranged from 2.0 to 7.0 $\mu g\ ml^{-1}$.

Performance of the initial variable set is shown in table 1. The model was revised and theoretical testing of the revised model found that it fitted the measured blood propofol concentrations significantly better than the original model in terms of MDPE, MDAPE and divergence, but with an increase in wobble. The variable set for the revised model was: V_1 (litre kg^{-1}) 0.2380, k_{10} (min^{-1}) 0.122, k_{12} 0.0406, k_{21} 0.0278, k_{13} 0.048 and k_{31} 0.0045.

Prospective testing of the revised model in another 20 patients found a deterioration in fit compared with its theoretical performance, and that the original model would have fitted these patients better in terms of MDPE but with a small increase in wobble (table 1). It was concluded that the original model based on the variable set of White and Kenny performed best in our patient population.

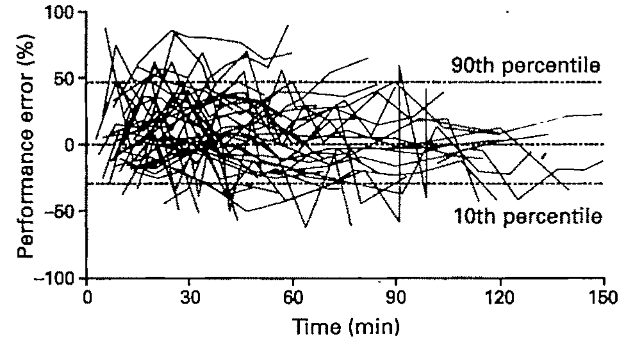

Figure 1 Performance error over time for the infusion phase in all patients using the original model.

Performance errors of the original model using data from all 40 patients in the study are shown as performance errors over time for the infusion phase of the study in figure 1. Performance of the original model in all 40 patients during the infusion phase was MDPE 2 %, MDAPE 21 %, divergence −17.1 % and wobble 7.2 %.

Comment

The pharmacokinetic data set of White and Kenny was found to adequately describe the disposition of propofol during target-controlled infusion in our adult population. This result in Oriental adults is in contrast with our finding in Oriental children [1]. Although it was originally thought that the model for paediatric patients indicated different requirements for propofol in Oriental children, a recent publication of propofol pharmacokinetics during infusion in children from the USA found pharmacokinetic variables which performed similarly in simulations of our paediatric variable set [6].

It is of interest that in our study we used arterial blood sampling, but found the model which had been modified using venous blood samples fitted well. This is probably because arterial sampling is more important when bolus doses are given and multiple early blood samples are obtained, but less important during a prolonged infusion such as was the case in the present study. In general, performance of the model in our patient population, as measured by MDAPE, was better than the performance of similar studies of propofol. This was because patients in our study conformed to a tightly defined range in terms of age and degree of obesity; a deterioration in fit would be expected when using the model in a more general patient population.

Although the mean performance of the model was satisfactory, inter-individual variability was wide in all measures of performance. The most important measure of performance of the system is MDAPE, this was as large as 69% during the infusion phase. Our revised model did not perform any better in terms of MDAPE, indicating that other factors not assessed in an algorithm based solely on body weight were responsible for the between-patient variability. The relatively small degree of wobble and divergence indicates that the system was better at maintaining a constant blood concentration than at predicting what that concentration would be. So long as the target concentration was adjusted according to clinical response, the system performed well in clinical practice.

There was a decrease in accuracy during the recovery phase, but this is not of major clinical relevance compared with the ability of the algorithm to maintain a stable blood concentration during the infusion phase. However, it does indicate that an alternative model may describe the recovery phase better. More blood sampling during the recovery period would be required to develop such a model than was performed during the current study.

In summary, we have found a system for propofol infusion described originally by White and Kenny to perform adequately in a healthy adult Oriental patient population. However, wide inter-individual pharmacokinetic variability meant the system did not always perform well in individuals. The model described the infusion phase of anaesthesia more accurately than the recovery phase.

Effect of ondansetron on nausea and vomiting after middle ear surgery during general anaesthesia

P. HONKAVAARA

Summary

The efficacy of ondansetron 4 mg and 8 mg was compared with placebo in the reduction of postoperative nausea, retching and vomiting (PONV) after middle ear surgery during general anaesthesia, in 75 patients, in a double-blind and randomized study. Both doses of ondansetron were predictors for a decrease in PONV and the number of doses of rescue antiemetic needed per patient (droperidol: from 0.72 in the placebo group to 0.32 in both the 4-mg and 8-mg groups). No reduction in PONV was observed in patients with a history of motion sickness, whereas in patients without a history of motion sickness, ondansetron reduced both the proportion of patients suffering from PONV from 53% to 20% ($P < 0.05$) and of those needing droperidol from 53% to 17% ($P < 0.05$). (*Br. J. Anaesth.* 1996; **76**: 316–318)

Key words

Vomiting, nausea. Vomiting, antiemetics. Surgery, otolaryngological.

In two recent studies, 62% and 80% of patients in placebo groups developed postoperative nausea and vomiting (PONV) after middle ear operations [1, 2]. Ondansetron has been found to be effective in preventing and treating PONV after general anaesthesia, and its safety profile is good with the recommended doses of 4 and 8 mg. Ondansetron is said to have a significant antiemetic effect on patients suffering from opioid-induced emesis. Middle ear surgery may disturb the vestibular system, and opioids increase vestibular sensitivity. On the other hand, vestibular stimulation increases the incidence of nausea and vomiting caused by opioids. The site of inhibitory action of ondansetron on PONV after middle ear surgery might be the nucleus tractus solitarius which has a high concentration of 5-HT_3 receptors.

The use of prophylactic ondansetron on PONV after middle ear operations has not been studied previously and the present study was designed to examine this area.

Methods and results

The Ethics Committee of the Otolaryngological Hospital approved the study, and informed consent was obtained from 75 patients undergoing middle ear surgery. All were ASA I–II, aged 15–62 yr. Exclusion criteria included: regular or temporary use of antiemetic drugs, and vomiting or retching within 24 h before operation. Twenty-five patients were allocated randomly to one of three groups; placebo, ondansetron 4 mg or ondansetron 8 mg. The design of the study was double-blind. On the preceding day, a history of motion sickness and PONV, and menstrual date were obtained.

A standard anaesthetic technique was used. Premedication comprised oxycodone 0.1 mg kg^{-1} and atropine 0.01 mg kg^{-1}. After insertion of an i.v. cannula, patients received the test drug in 5–7 min (ondansetron 4 mg or 8 mg (Zofran) or placebo diluted to 100 ml in 0.9% NaCl) in a double-blind manner. Anaesthesia was induced with thiopentone 5 mg kg^{-1}, preceded by fentanyl 2 μg kg^{-1}, which was given thereafter during surgery as 50-μg doses. Alcuronium 2–2.5 mg was used for "precurarization" and tracheal intubation was facilitated with suxamethonium 1.5 mg kg^{-1}. Anaesthesia was maintained with isoflurane (inspiratory concentration 0.5–1.5 vol%, mainly 0.75 vol%) and 66% nitrous oxide (which was replaced by air before closing of the tympanic membrane) in oxygen. Arterial pressure and heart rate were maintained within 20% of preanaesthetic values. End-tidal carbon dioxide concentration was kept at 5.0–5.5%. Vecuronium was used for neuromuscular block and residual block was antagonized with neostigmine 2 mg and glycopyrronium 0.4 mg. Arterial pressure, capnogram, electrocardiogram, haemoglobin oxygen saturation (Sp_{O_2}) and neuromuscular block were monitored routinely.

Postoperative pain was treated with diclofenac 1 mg kg^{-1} twice daily or paracetamol 10 mg kg^{-1} four times daily in patients who did not tolerate diclofenac. In addition, oxycodone 50 μg kg^{-1} i.v. or 100 μg kg^{-1} i.m. was used if needed for additional analgesia.

A trained nurse, who was unaware of the nature of the study drug, assessed the incidence of nausea, retching and vomiting at the following times: 0–2, 2–6, 6–12, 12–18 and 18–24 h after the end of anaesthesia. Droperidol 10 μg kg^{-1} i.v. or i.m. was given for vomiting, retching or prolonged nausea, at a minimum interval of 30 min.

Table 1 Effect of ondansetron (4 mg and 8 mg) after middle ear surgery in patients without a history of motion sickness on PONV and the need for rescue antiemetics (number of patients). $*P < 0.05$ (Fisher's exact test), $**P < 0.01$ (Mann–Whitney U)

	Placebo	Ondansetron
Patients (n)	19	30
Sex (M/F)	11/8	18/12
Ondansetron 0/4 mg/8 mg	19/0/0	0/16/14
Patients free of PONV (%)	47	80*
Patients suffering from retching or vomiting (%)	37	10*
Patients needings droperidol (%)	53	17*
Doses of droperidol needed per patient (median (range))	1 (0–3)	0 (0–2)**

Patients in the placebo and ondansetron groups did not differ significantly in age, weight, sex, phases of the menstrual cycle, details of anaesthesia, duration of anaesthesia or operation, mean concentration of inspired isoflurane, total dose of fentanyl given, dose of lignocaine given topically during surgery or need for oxycodone after operation. There were no side effects from the test drug in any of the groups.

After surgery, 12 %, 12 % and 24 % of the patients in the placebo group suffered from nausea, retching and vomiting, respectively. The corresponding values in the ondansetron 4 mg group were 16 %, 4 % and 8 %, and in the 8 mg group, 4 %, 16 % and 16 %.

In the search for factors associated with PONV, logistic regression analysis revealed that ondansetron, both 4 mg ($P < 0.05$) and 8 mg ($P < 0.05$), a history of motion sickness ($P < 0.05$) and female sex ($P < 0.01$) were predictors of PONV and the need for rescue antiemetic, but the amount of oxycodone was not a predictor of these effects.

Twelve patients in the placebo group needed droperidol, but only six and seven patients in the ondansetron 4 and 8 mg groups, respectively. The need for rescue antiemetic, in mean doses per patient, was 0.72 (0.89) in the placebo group, 0.32 (0.63) in the ondansetron 4 mg and 0.32 (0.56) in the ondansetron 8 mg group.

In the 49 patients *without a history of motion sickness*, prophylaxis with ondansetron 4 mg and 8 mg decreased both the proportion of patients suffering from PONV and the need for droperidol (table 1).

Comment

The main finding in this study was that prophylaxis with ondansetron reduced PONV and the need for droperidol. There was a marked reduction in the number of patients suffering from PONV and also the need for droperidol in those without a history of motion sickness.

The overall percentage of placebo-treated patients reporting emetic symptoms in this study was in agreement with two recent studies on PONV after middle ear surgery under general anaesthesia [1, 2].

The mechanism of PONV after ear operation is still obscure. Increased middle ear pressure caused by nitrous oxide has been postulated as one of the mechanisms. This was unlikely in the present study as nitrous oxide was replaced by air well before closing of the tympanic membrane and thus no pressure was generated in the middle ear from diffusion of nitrous oxide.

One of the causes of PONV after middle ear surgery could be the physical stimulus caused by the otologist drilling and irrigating the bone adjacent to the inner ear. High levels of noise caused by drilling and suctioning have been reported in ear surgery, and noise exceeding 107 dB(A) has been measured in the mastoid cavity [3]. The otologist also causes low frequency vibrations, especially when using a slowly rotating cutting burr. These vibrations may act in the same way as infrasound on the vestibular system. It has been shown that low-frequency sound stimulation provokes postural instability in patients undergoing surgery for chronic otitis media [4].

This action of noise is termed the Tullio phenomenon, and is caused by loud sound waves activating the vestibular part of the inner ear [4]. The postulate that physical stimulation is one of the causes of a high incidence of PONV after middle ear surgery is supported by the fact that transdermal hyoscine, a drug used in motion sickness, is more potent in reducing PONV [1, 2] than ondansetron, which lacks an anti-motion sickness effect [5].

Zacopride, another 5-HT$_3$ antagonist, overcomes the cognitive impairment which occurs with hyoscine [6]. Thus the combination therapy of transdermal hyoscine and a 5-HT$_3$-antagonist should cover patients with and without motion sickness and may lead to less PONV with lesser side effects, but this hypothesis requires evaluation before it can be recommended.

We conclude that the use of prophylactic ondansetron reduced PONV and the need for antiemetics after surgery of the middle ear under general anaesthesia. Patients without a history of motion sickness benefited more from this prophylaxis. We recommend a dose of 4 mg, as increasing the dose to 8 mg did not decrease PONV or the need for rescue antiemetic.

Extradural analgesia with clonidine and fentanyl compared with 0.25% bupivacaine in the first stage of labour

D. J. BUGGY AND C. MACDOWELL

Summary

Conventional extradural analgesia during labour with 0.25–0.375% bupivacaine may induce motor weakness and subjective sensory deficit, reducing maternal satisfaction. Even in a regimen for ambulatory extradural analgesia (0.1% bupivacaine–fentanyl 2 μg ml^{-1}), a potential for proprioreception impairment exists, which may impair safe ambulation. We have combined fentanyl with clonidine for extradural analgesia in labour, and compared its effects with 0.25% bupivacaine, in a randomized, double-blind study. We studied 28 women requesting extradural analgesia for labour; they were allocated randomly to either group 1, who received clonidine 120 μg with fentanyl 50 μg, or group 2, who received bupivacaine 25 mg. Detailed clinical neurological examination was undertaken 30 min later. Pain was assessed subjectively using a 10-cm visual analogue scale (VAS). There were no significant differences in VAS between the groups at any time. Median onset of analgesia was longer in group 1 (24.3 (interquartile range 20–35) compared with 17.5 (15–25) min) ($P < 0.05$) and 79% of group 1 *vs* 86% of group 2 patients reported a high degree of satisfaction with extradural analgesia. Patients in group 2 had a much higher incidence of motor weakness ($P < 0.01$), impaired perception of pinprick ($P < 0.01$) and impaired distal joint proprioception ($P < 0.05$) than group 1. We conclude that clonidine 120 μg–fentanyl 50 μg provided comparable extradural analgesic efficacy as 0.25% bupivacaine for the first stage of labour. Furthermore, unwanted neurological effects were significantly less. (*Br. J. Anaesth.* 1996; **76**: 319–321)

Key words

Anaesthetics local, bupivacaine. Anaesthetic techniques, extradural. Analgesics opioid, fentanyl. Analgesia, obstetric. Sympathetic nervous system, clonidine.

Local anaesthetics, most commonly bupivacaine, administered repeatedly for extradural analgesia in labour may cause progressive motor block even if relatively dilute concentrations are used. This has resulted in decreased maternal satisfaction with extradural analgesia [1]. The introduction of ambulatory extradural analgesia, using very dilute concentrations of local anaesthetics, in combination with adjuvants such as fentanyl and adrenaline, has allowed greater mobility and maintenance of near normal somatic sensation [2]. However, clinical impairment of distal joint proprioception after an ambulatory extradural regimen has been reported recently, giving rise to anxiety that safe ambulation may be impaired even in the presence of apparently normal lower limb motor function [3]. Clonidine, in common with opioids, has successfully enhanced bupivacaine-induced extradural analgesia in labour [4], but its use alone for postoperative extradural analgesia has been disappointing. Clinical trials of extradural opioids alone have yielded conflicting results [5]. However, intrathecal opioids, used alone or as part of a combined spinal–extradural technique, seem promising [5].

No prevous study has assessed the impact of combining fentanyl with clonidine, without local anaesthetic, to provide extradural analgesia for the first stage of labour. We hypothesized that unwanted neurological effects should be greatly diminished with this combination. The purpose of this study, therefore, was to compare the analgesic efficacy and effect on proprioception and motor weakness of combining these two analgesic adjuvants, with 0.25% bupivacaine, for extradural analgesia in labour.

Methods and results

After obtaining informed consent and local Ethics Committee approval, we studied 32 women ($n = 22$ nullipara) in established labour (minimum 3 cm cervical dilatation, 80% cervical effacement). Patients with more than 6 cm cervical dilatation, intercurrent disease or those with a complicated pregnancy were excluded. No patient had received any analgesia before the extradural.

After administration of Hartmann's solution 500 ml i.v. to the patient, an extradural cathether was sited at the L2–3 or L3–4 intervertebral space. Patients were allocated randomly to one of two groups, and extradural analgesia was administered in a double-blind design, that is the anaesthetist,

midwives and patients were unaware of which analgesic regimen was being used. The hospital pharmacist prepared the study solutions in coded 10-ml syringes, and arranged randomization according to computer-generated random numbers. Patients in group 1 received clonidine 120 µg (0.8-ml solution) and fentanyl 50 µg (1-ml solution), made up to 10 ml with normal saline. These doses were chosen because previous studies on postoperative patients found them to be safe and effective [2, 4, 6]. Patients in group 2 received bupivacaine 25 mg in a 10-ml solution. No test dose was given. If patients were receiving an oxytocin infusion, it was stopped during insertion of the extradural and until analgesia to half the baseline visual analogue scale (VAS) score was achieved. Non-invasive arterial pressure and continuous fetal heart monitoring were maintained in all patients during labour.

Subjective perception of maximum pain intensity during uterine contraction was recorded on a 10-cm VAS before insertion of the extradural cathether and at 5-min intervals thereafter for the first 40 min, and then at 60- and 90-min intervals. The time taken for the baseline VAS to be reduced by 50 % was noted retrospectively. Subsequent analgesia was provided by an extradural infusion of 0.1 % bupivacaine, prepared by the anaesthetist and commenced by the midwife at a rate of 3–6 ml h^{-1}, at her discretion, if VAS scores increased to > 4 or if patient discomfort increased. The time from the initial bolus to commencement of this infusion was noted as the duration of analgesia. After delivery, overall satisfaction with extradural analgesia was recorded by the patient on a four-point scale: excellent, good, fair or poor. If analgesia was inadequate, a 5-ml bolus of 0.25 % bupivacaine was given.

Thirty minutes after the initial bolus, a detailed, clinical neurological examination of the lower trunk and limbs was performed by the same observer, as described previously [3]. Maternal arterial pressure (standing and recumbent), and any pruritus or shivering, and sedation levels were also recorded. Sedation was graded on a four-point scale: awake, drowsy, dozing (eyes shut intermittently) or asleep (but rousable on being spoken to). Hypotension was defined as a decrease in systolic arterial pressure of at least 30 %, and was treated by giving another 250 ml of Hartmann's solution i.v., repeated as necessary. Fetal heart rate was noted throughout labour using a cardiotocograph. After delivery, neonatal Apgar scores were recorded at 1 and 5 min.

The groups were similar in physical and labour characteristics. Four patients were subsequently lost from the study ($n = 3$ multiparae) because delivery occurred within 60 min of extradural catheter insertion. There was a comparable degree of analgesia, as assessed by VAS, between the two groups at all times. Median onset of analgesia (defined as the time taken for the baseline VAS to be reduced by 50 %) was significantly longer in group 1 (24.3 (interquartile range 20–35) *vs* 17.5 (15–25) min) ($P < 0.05$). When established, however, duration of analgesia provided by both regimens was similar. Median consumption of 0.1 % bupivacaine infusion was similar in each group. Eleven (79 %) patients in group 1 and 12 (86 %) in group 2 recorded an "excellent or good" overall satisfaction rating for their analgesia (table 1).

5 min	9.25 (8–10)	9.0 (8–10)
Satisfaction (*n* (%))	11 (79 %)	12 (86 %)
Muscle power (MRC grade < 3) (*n*)	1	8**
Impaired proprioception (*n*)	4	10*
Impaired vibration sense (*n*)	2	4
Romberg's sign (+) (*n*)	2	6
Impaired pinprick perception (T10–L4)	0	7**
Hypotension (*n*)	8 (57 %)	4 (29 %)

Patients in group 2 had significantly more motor weakness and impaired perception of pinprick, characterized by anaesthesia (no sensation) or analgesia (sharp stimulus perceived as blunt). All patients in group 1 had preserved spinothalamic-mediated sensation (pinprick and temperature), in spite of reporting significant analgesia for labour pain. The incidence of impaired proprioception was also significantly higher in group 2, but differences in the other posterior column sensory modalities were not significant (table 1). Median sensory level was T10 in both groups.

There were no significant differences between groups in lowest systolic pressure, or the incidences of commonly reported side effects of the drugs used. Eight of 14 patients in the clonidine–fentanyl group had hypotension compared with four of 14 in the bupivacaine group. However, because of the low overall incidence of side effects, together with the low numbers studied, the power of this study to detect true differences in these side effects was only 30 % for sedation and 45 % for hypotension.

Comment

We chose to compare a clonidine–fentanyl regimen with 0.25 % bupivacaine, rather than an ambulatory regimen of 0.1 % bupivacaine, because we found that the latter has suboptimal, short-lived analgesia when not combined with spinal anaesthesia [3]. In addition, favourable comparison with the analgesic efficacy of the higher dose of bupivacaine would be desirable with a new regimen. We did not allow our patients to walk as we were unaware which solution was used, and felt that 0.25 % bupivacaine would be unsafe.

Our data suggest that the side effect profile was low, with 11 patients unaffected by sedation; the remaining three patients showed only mild degrees of sedation. This contrasts with other studies of patients in labour using bupivacaine and clonidine, in which 50 % of patients had sedation scores of 2 or more [4]. Although hypotension occurred at some time during the study, it was twice as common in patients receiving the clonidine–fentanyl mixture, no patient reported symptoms attributable to it and no patient had postural hypotension. In our study, the degree of sedation and hypotension was mild. Pruritus was not a feature in our study. In common with other reports using these agents extradurally [2], our median neonatal Apgar scores were very satisfactory (table 1).

The occurrence in our bupivacaine-free group of a degree of posterior column impairment, together with the absence of segmental sensory changes, despite satisfactory analgesia for labour, is intriguing. Extradural clonidine prolongs the sensory and motor block induced by bupivacaine [4], but it is not known if it has intrinsic inhibitory effects on axonal transmission. Fentanyl, and surprisingly, normal saline administered extradurally, cause segmental sensory deficit, but again the mechanism is unclear [2].

A study of the neurological status of the lower limbs of women in labour receiving extradural analgesia with 0.1 % bupivacaine and fentanyl 2 $\mu g\ ml^{-1}$ was conducted in 50 primigravidae, and there was a high incidence of posterior column sensory impairment [3]. Although the present study did not directly compare them, it may be safer for patients receiving clonidine–fentanyl to walk than a group receiving an ambulatory regimen (e.g. 0.1 % bupivacaine with fentanyl 2 $\mu g\ ml^{-1}$), because of decreased unwanted neurological impairment. Moreover, a comparison of extradural fentanyl alone with 0.04 % bupivacaine, adrenaline 1.7 $\mu g\ ml^{-1}$ and fentanyl 1.7 $\mu g\ ml^{-1}$ (BAF) found that 70 % of patients receiving each regimen could walk, but motor weakness and orthostatic hypotension occurred in significantly more patients in the BAF group [6]. We acknowledge, however, that experience of more than 7000 cases of ambulatory extradural analgesia recorded no incidence of falling. Such large series of safe reports on the use of the ambulatory regimen of extradural analgesia suggest that the theoretical risk of falling from impaired posterior column sensation is minimal. In addition, our patient numbers were small, and larger studies are required to confirm the safety of the clonidine–fentanyl regimen in terms of its potential side effects.

CASE REPORTS

Sudden onset of subarachnoid block after subdural catheterization: a case of arachnoid rupture?

D. W. Elliott, F. Voyvodic and P. Brownridge

Summary

We describe a patient who received an apparently uneventful extradural block in labour but developed rapid extension of neural block within minutes of receiving her first incremental dose 2 h later. Computed contrast tomography revealed radio-opaque dye within both the subdural and sub-arachnoid spaces, but none within the extradural space. This case report demonstrates that subdural spread of low-dose local anaesthetics is not always clinically distinguishable from extradural analgesia and that the arachnoid membrane may subsequently perforate with potentially serious consequences. (*Br. J. Anaesth* 1996; **76**: 322–324)

Anaesthesia, obstetric. Anaesthetic techniques, extradural. Complications, subarachnoid block.

Case report

A 23-yr-old nulliparous Asian woman requested extradural analgesia for pain relief in early labour. The patient was in good health and there were no contraindications to the procedure. She was of slim build and her spine was easily palpable. The operator (D.W.E.) had previously performed approximately 50 extradurals without complication. With the patient in a sitting position, an 18-gauge Tuohy needle was inserted into the extradural space at the L3–4 interspace without difficulty. Loss of resistance to air was detected at 4 cm and an extradural catheter (Portex, Kent) was inserted with minimal resistance. After removal of the Tuohy needle, however, it was estimated that no more than 1 cm of catheter was lying within the extradural space. Consequently, the procedure was repeated using the same interspace and a new catheter inserted without difficulty such that an estimated total of 4 cm lay within the extradural space. The extradural needle was not rotated on either attempt and the patient did not complain of pain, paraesthesia or headache during insertion of the catheter. Nothing could be aspirated from the needle or catheter on either occasion.

After a further negative aspiration test with the patient lying on her side, a 3-ml dose of 0.25% bupivacaine was given via the catheter. This test dose produced no detectable sensory or motor changes and after 5 min another 7 ml of the same solution were given. Satisfactory analgesia was achieved approximately 5 min later and there was no change in arterial pressure. When so instructed, the patient was able to raise both legs from the surface of her bed. No further formal assessment of the height of the block was made.

Two hours later, further analgesia was requested. With the patient in a semi-recumbent position, and after a negative aspiration test, a pre-mixed proprietary preparation containing bupivacaine 12.5 mg and pethidine 25.0 mg in saline 10 ml (Delta West, Perth, Australia) was injected by the attending midwife via the extradural catheter. Five minutes later, the patient complained of nausea, shortness of breath and numbness in her hands and face. An urgent request by the midwife for an anaesthetic review was met within minutes.

On examination, the patient was found to be drowsy but responsive to questions and commands. She was unable to move either of her lower limbs but retained a weak bilateral handgrip and was still able to lift her head from the pillow. Anaesthesia to cold was present over the entire chest wall below the clavicles but there was no sensory loss over the face and neck. Marked nystagmus was observed. The pupils were small and equal, and it is possible that bilateral ptosis was present, although it was difficult to be certain because of the patient's ethnic origin and her state of drowsiness. There was no obvious injection of the sclerae and both nostrils were patent, but the presence of a bilateral Horner's syndrome could not be excluded.

During this period of assessment, the patient remained remarkably calm and co-operative. Her arterial pressure did not change and there were no signs of respiratory depression or fetal distress. Despite complaining of some shortness of breath, her vital capacity was recorded as 1.5 litre. She was given supplementary oxygen and pulse oximetry revealed an oxygen saturation of 99%. In view of these findings, it was decided not to administer naloxone unless there was any deterioration in her state of consciousness or ventilation.

A provisional diagnosis of subarachnoid catheter migration was made and instructions given that further analgesia would be administered only by an anaesthetist. Over the next 2 h there was complete recovery of neural function. Five further top-up doses consisting of 0.25% bupivacaine 2 ml were

Nerve roots of cauda equina
Dura
Contrast medium in subarachnoid space
Arachnoid
Air
Contrast
confined within subdural space

Figure 1 Left: CT scan at L1–2. Contrast medium is layered posteriorly in the subarachnoid space with the cauda equina nerve roots clearly identified anteriorly. A further collection of contrast medium and air distends the subdural space. The extradural space is free of contrast medium. Right: diagrammatic representation of the CT.

given for pain during the rest of her labour. On each occasion, analgesia occurred within the duration of a contraction and lasted for an interval of 45–60 min. Incomplete motor block of the lower limbs returned after each injection. Eight hours after insertion of the extradural catheter, a healthy baby was delivered with the aid of outlet forceps.

Although we strongly suspected on clinical grounds that the catheter tip had ultimately become situated within the subarachnoid space, we were puzzled why the response to the initial dose had been so uneventful. In which compartment(s) had the catheter been originally placed? Did the catheter migrate from the extradural or subdural space, or was it in the subarachnoid space from the outset? To try and answer these questions we felt it would be useful to confirm the position of the catheter radiologically. The patient agreed to this proposal and gave her informed consent for computer tomography (CT) using contrast medium.

Four hours after delivery the patient was transferred to the CT scanner and 3 ml of iodinated contrast medium (iopamidol 300 mg ml^{-1}) were introduced via the extradural catheter; 5-mm thick contiguous axial CT scans were then performed through the upper lumber spine. This showed contrast medium only within the subdural and subarachnoid spaces while the extradural space was entirely contrast-free (fig. 1).

The day after delivery, the patient developed typical features of a dural puncture headache which gradually became more severe. An extradural blood patch was performed on day 4 and her headache disappeared after 3 h. She remained headache-free when discharged from hospital 2 days later.

Discussion

Subdural catheterization is a well recognized complication of extradural analgesia with an estimated incidence, according to one retrospective study, of 0.8% [1]. The diagnosis in that study, however, was based solely on clinical criteria and was not confirmed radiologically. The true incidence of subdural catheterization, therefore, remains unknown because a definitive diagnosis depends on CT imaging, an investigation that is justified only if catheter misplacement has been suspected clinically.

While two attempts were made to site the extradural catheter in our patient, the procedure was straightforward on both occasions; the first catheter was pulled out accidentally when the needle was removed. There was certainly no reason to believe that the dura had been perforated, injured or otherwise predisposed to catheter misplacement on either occasion, although such events can never be entirely excluded.

It has been claimed by various authors that subdural local anaesthetic spread can be diagnosed, or at least strongly suspected, on clinical grounds. According to Collier [2] for example, subdural spread is typically accompanied by: relatively slow onset of neural block (i.e. 15–20 min with further progression over the next 20 min); limited motor block; only moderate hypotension; progressive respiratory depression and inco-ordination rather than sudden apnoea; and recovery after 2 h [2]. Other clinical clues have also been suggested, such as: exaggerated hypotension and unexpectedly high motor block [1, 3, 4]; relative sparing of motor function in the lower limbs [4]; unilateral block [5]; the presence of a Horner's syndrome [3]; and, possibly, acute headache during injection [6]. Without radiological confirmation, however, the reliability of these clinical signs in distinguishing between extradural, subdural and subarachnoid injection is conjectural.

One of the important features in this case report is that our patient displayed none of the above symptoms or signs after the initial therapeutic dose.

Aspiration of both needle and catheter was negative, and there was no abnormal response to the test dose. Thus there were no grounds to believe that the catheter was other than correctly sited in the extradural space. Yet the CT scan clearly demonstrated no spread within the extradural space. This finding implies, therefore, that subdural spread of local anaesthetic drugs when given in *low* dosage is not necessarily clinically distinguishable from extradural or even subarachnoid spread.

In a previous case report, we described an obstetric patient in whom an extradural catheter was subsequently shown to have been confined solely within the subdural space [6]. We now report a patient in whom we believe the catheter was initially within the subdural space but later became situated intrathecally, as postulated in the review by Reynolds and Speedy [7]. While it has been found to be impossible to puncture the intact postmortem dura with a Portex catheter, the thinner arachnoid membrane is easily perforated [8]. Thus it is not difficult to appreciate how readily transarachnoid migration of a subdural catheter might occur in clinical practice.

In our patient, the clinical response to subsequent doses was so distinct from that following the initial dose that we felt confident in assuming that the catheter had become situated intrathecally. This was confirmed not only radiologically but also by the fact that she later developed a spinal headache. An alternative explanation might be that the side holes of the extradural catheter were situated within both the subdural and subarachnoid spaces from the outset and that any disparity in clinical response depended entirely on the vagaries of differential flow [9, 10]. However, the fact that our patient responded so consistently to subsequent doses, and that the extradural space was altogether free of radio-opaque dye makes this alternative explanation, we believe, exceedingly unlikely.

Fortunately, the initial intrathecal dose was not sufficient to cause severe respiratory or circulatory depression in our patient and resuscitation was not required. This is now the second time a mixture of bupivacaine 12.5 mg and pethidine 25 mg has been given intrathecally in our unit without causing serious harm or injury [11]. Our experience thus supports the contention that extradural management during labour is associated with an intrinsically greater margin of safety when local anaesthetics are used in low doses [12].

If our interpretation of events concerning this case report is correct, then presumably a subdural catheter can perforate the arachnoid membrane and become situated within the subarachnoid space at any time. This, too, has important implications. Although our patient received intermittent bolus doses, there is no reason to believe that other regimens, such as continuous infusions or patient-controlled extradural analgesia, are immune to transarachnoid migration. Our case report helps to explain just how easily subdural catheter placement may escape notice, and reinforces the need to meet recommended standards of supervision and management among all patients receiving extradural analgesia in labour, irrespective of the drug delivery system.

Elective forceps delivery and extradural anaesthesia in a primigravida with portal hypertension and oesophageal varices

J. A. Heriot, C. M. Steven and R. S. Sattin

Summary

The use of extradural analgesia to avoid straining in a primigravida with portal hypertension and secondary oesophageal varices is described, together with a discussion of the advantages and disadvantages of this approach. (*Br. J. Anaesth.* 1996; **76**: 325–327)

Key words

Anaesthetic techniques, extradural. Anaesthesia, obstetric. Complications, hypertension. Complications, oesophageal varices.

Case report

A 31-yr-old Caucasian primigravida presented for antenatal care at 11 weeks' gestation. Past medical history included a diagnosis of portal vein hypertension secondary to idiopathic portal vein thrombosis, having presented with haematemesis at 4 yr of age. She was found to have hepatosplenomegaly and, at 5 yr of age, a splenectomy was performed to treat thrombocytopenia. At booking, her arterial pressure was 120/70 mm Hg, weight 57.3 kg and height 1.7 m.

She suffered a small haematemesis at 8 weeks' gestation which was treated by admission and observation in hospital. Although her portal hypertension was regularly followed-up at a specialist teaching hospital, she wished to have her baby delivered locally. She was seen in the antenatal clinic by a consultant anaesthetist to discuss pain relief in labour. The patient said that she did not want to be immobilized by an extradural but understood that an elective forceps delivery was planned. Prophylactic endoscopic banding of her oesophageal varices, which were moderately large from the gastro-oesophageal junction to the mid-oesophagus, was performed uneventfully at 16, 25 and 31 weeks' gestation.

She was admitted to the labour ward in spontaneous labour at term plus 5 days. Vaginal examination demonstrated intact membranes, 4 cm cervical dilatation and a thinning cervix. The medical team and intensive care unit were informed of her admission and a Sengstaken–Blakemore tube was available. An i.v. infusion was commenced and blood obtained for investigation and cross-matching. Full blood count, clotting and liver function tests were normal. An extradural was sited at the L2–3 interspace, in the left lateral position, using a 16-gauge Tuohy needle with loss of resistance to saline. Analgesia was established using a solution of 0.1 % plain bupivacaine and fentanyl 2 μg ml^{-1}; 10 ml was given as the initial bolus with 10–15-ml supplementary doses.

The patient's membranes ruptured after 4 h of labour and an i.v. infusion of oxytocin was commenced after 8 h (the delay in these events was initial reluctance by our patient of any methods to augment labour). The extradural was maintained subsequently with increments of 0.25 % plain bupivacaine to prevent any desire to "bear down". The first stage lasted 12 h 36 min. The second stage lasted 41 min and a live male infant weighing 3.48 kg, with Apgar scores of 7 and 9, was delivered vaginally by elective use of Anderson forceps. A physiological third stage lasted 18 min, the placenta was healthy, complete and weighed 600 g. Uterine contraction was satisfactory and the decision was made not to administer the combination of ergometrine and syntocinon in order to avoid the risk of inducing hypertension and the autotransfusion effect of more aggressive uterine contraction. Total blood loss was 300 ml.

The puerperium was uneventful with no haematemesis or change in liver function.

Discussion

In a pregnant woman with known oesophageal varices, the decision to deliver the fetus by lower segment Caesarean section or vaginally is controversial. It is already known that pregnant women with extrahepatic portal vein obstruction have a fetal loss rate of one-third and a 400 times increased mortality rate [1]. However, although these cases are rare, these patients have normal fertility and usually normal liver function, and the main hazard is variceal haemorrhage, unlike those with chronic active hepatitis and portal hypertension who also risk developing acute hepatic failure.

As in our patient, variceal bleeding from extrahepatic pre-sinusoidal portal hypertension usually occurs first in childhood or adolescence and is the

commonest mode of presentation. The first haemorrhage often occurs at about 4 yr of age if the pathology has a neonatal origin such as umbilical or intra-abdominal infection, or septicaemia [2]. This group normally tolerates haemorrhage well as they tend to have good cardiovascular and hepatic reserve and cessation of bleeding occurs without intervention in up to 20 % of cases [3].

There is varied opinion on the risk of bleeding from varices during pregnancy itself. Blood volume in pregnancy increases by a maximum of 40–45 %. This volume is taken up partially by the splanchnic system and great veins, and increases right heart pressure, thereby increasing the portal venous pressure in the later stages of pregnancy. Transient oesophageal varices may develop in two-thirds of healthy pregnant women [4]. As the fetus grows, venous return is reduced via the inferior vena cava. Classic studies in 1963 and 1964 [5, 6] indicated that the inferior vena cava is normally occluded in the supine position in late pregnancy and that venous return occurs via the azygos and vertebral veins. Although this inferior vena cava occlusion is greatly relieved in the lateral position, collateral flow through the pathological varices is increased and so is the risk of their bleeding [7]. Another view is that from a comprehensive review by Britton [8], who concluded that fatal haemorrhage from pre-existing oesophageal varices is not more likely to occur during gestation and that it is not predictable on the basis of individual history of bleeding. When haemorrhage does occur it is usually in the second trimester and this may be linked to the maximum expansion in total blood volume at the end of the second trimester [8].

Various methods have been used to treat variceal haemorrhage, including the Sengstaken–Blakemore tube, shunt procedures, endoscopic sclerotherapy [9–11] and, more recently, banding. Our patient had a haematemesis at 8 weeks' gestation and it was decided to apply bands to the varices using endoscopy. This was performed three times and it was felt that the advantages of reducing the risk of life-threatening haemorrhage outweighed possible disadvantages. This patient had no further haematemeses during pregnancy or in the postpartum period.

Another potential cause of mortality is the relationship between the pregnant patient with portal hypertension and ruptured splenic artery aneurysm. This event can mimic other obstetric emergencies such as placental abruption, uterine rupture or an embolic event. Although the incidence in pregnancy is lower than in the general population (20 %), this may be explained in that many patients with portal hypertension rarely become pregnant [12].

We would recommend vaginal delivery under extradural analgesia with avoidance of any straining by the mother, which still allows progression to lower segment Caesarean section if necessary [13]. Treatment for active bleeding, including invasive monitoring, large-gauge cannulae, cross-matched blood, fresh frozen plasma, platelets, additional blood products, a Sengstaken–Blakemore tube and a vasopressin infusion must be available.

To avoid straining the most effective analgesia is ideally extradural analgesia with elective forceps or Ventouse extraction in the second stage. There should be no contraindications to extradural analgesia. One previous study described a pregnant patient with oesophageal varices secondary to portal hypertension from chronic schistosomiasis who also had thrombocytopenia. This patient had a splenectomy during pregnancy and this allowed an extradural to be performed for delivery [7]. Alternatively, delivery by forceps at commencement of the second stage using pudendal block anaesthesia has been reported, although the forceps delivery itself can be difficult if the head is still relatively high or in the occipito–posterior position, or both. This should avoid the marked increase in portal pressure which occurs in the second stage. Even in normal patients, contraction of the diaphragm can raise portal pressure to three times normal [14].

It is recognized that with portal hypertension and oesophageal varices the already engorged extradural veins of pregnancy may be dilated further. This increases the risk of a "bloody tap" when siting the extradural. Apart from positioning the patient in the lateral position for the procedure, and possible slight head-down tilt to reduce extradural vein pressure, there is little to reduce this problem. With extradural vein engorgement, the possibility of vascular absorption of the local anaesthetic with systemic toxic reaction could be increased. However, a study of extradural anaesthesia in patients with portal hypertension (although using mepivacaine rather than bupivacaine) did not show an increased risk [15].

Extradural analgesia was commenced in our patient with a dilute solution containing 0.1 % plain bupivacaine and fentanyl 2 $\mu g\ ml^{-1}$. Early in labour this produced good analgesia with a degree of independence of movement in the patient. As labour progressed, this mixture did not eliminate completely the desire to perform a Valsalva manoeuvre with the onset of each contraction and so this was changed to 0.25 % plain bupivacaine. This prevented the patient mobilizing but achieved the objective of removing any attempt to strain.

We believe lower segment Caesarean section should be reserved for obstetric indications [16–18] and where there is a contraindication to extradural anaesthesia. Theoretical advantages include a planned, elective time of delivery and possibly easier manipulation of the cardiovascular system under general anaesthesia. However, because of portal hypertension there may be dilated, aberrant vessels at Caesarean section, or adhesions from previous shunt surgery, and haemorrhage with hypotension may be as much a problem as the risk of hypertension. If a general anaesthetic is given, the patient should be treated as having a "full stomach" which usually involves extubation of the trachea with the patient awake and in the lateral position.

Spinal anaesthesia should probably be avoided as the block is usually dense, and hypotension from sympathetic block often occurs. Ephedrine may counteract this but it may cause tachycardia and hypertension. However, if ephedrine is avoided in this type of patient and further haemorrhage occurs then the subsequent hypotension may be profound.

Combined spinal and extradural anaesthesia can produce satisfactory analgesia with maintenance of some mobility, even if this is the ability to move around the bed rather than the labour ward. However, in extrahepatic portal hypertension the potential for some of the local anaesthetic required for the extradural to spread through the small dural puncture is even higher than usual [19] because of engorged extradural veins. The risk of a total spinal would further complicate the management of this patient.

The active management of the third stage with Syntometrine is to reduce the risk of postpartum haemorrhage. However, in this situation the potential effect of more forceful, iatrogenic, uterine contraction squeezing a larger blood volume to the inferior vena cava and then to the oesophageal varices was considered to outweigh that of haemorrhage. We allowed a physiological third stage as our patient's uterine contraction was effective.

Despite provision for a potentially serious outcome, this patient's antenatal and postnatal care were without incident. There is an argument for delivery of such a mother in a specialized obstetric–liver unit but this patient was extremely reluctant to travel outside the local vicinity. She had portal hypertension but no evidence of hepatic failure. Mandatory specialist referral is indicated in such cases for hepatic encephalopathy (grade 2–4), elevated prothrombin ratio (> 2 times normal control), metabolic acidosis (blood pH < 7.3), hypotension, hyponatraemia and thrombocytopenia. These features were not present in our patient.

Bilateral severe pain at L3–4 after spinal anaesthesia with hyperbaric 5% lignocaine

R. RODRÍGUEZ-CHINCHILLA, A. RODRÍGUEZ-PONT, T. PINTANEL AND F. VIDAL-LÓPEZ

Summary

We describe a case of transient pain in both legs after spinal anaesthesia with a hyperbaric solution of 5% lignocaine delivered in a single bolus through a 22-gauge Quincke needle. The patient remained in a supine decubitus position throughout surgery and 31 h later pain was referred bilaterally to the L3 and L4 dermatomes. (*Br. J. Anaesth.* 1996; **76**: 328–329)

Key words

Anaesthetic techniques, subarachnoid. Complications, neurological. Anaesthetics local, lignocaine.

Lignocaine 5% in hyperbaric solution has long been used for subarachnoid anaesthesia and was considered safe [1] until reports of permanent neurological complications began to appear in 1991, after the introduction of continuous spinal anaesthesia through microcatheters [2, 3]. Microcatheters were blamed mainly at first, until cases of severe transient pain in both lower extremities were reported later after spinal anaesthesia with 5% lignocaine in hyperbaric solution delivered in a single dose [4, 5]. We describe a case involving a patient who developed severe pain in both legs the second day after spinal anaesthesia with 5% lignocaine.

Case report

A 66-yr-old man, 159-cm tall and weighing 80 kg, was scheduled for removal of a penile implant that had caused skin ulceration. The patient had chronic bronchitis but there was no history of neurological problems. Blood clotting and chemistry were normal. Prior history included repair of an umbilical hernia, haemorrhoidectomy and implantation of a penile prosthesis on two occasions. Anaesthesia for all four operations comprised spinal injection of 0.5% bupivacaine. On this occasion, the patient was seated and the lumbar area washed with povidone. A spinal needle with a 22-gauge Quincke point was inserted easily at the L3–4 interspace. Correct placement was confirmed by free flow of CSF. We then administered 5% lignocaine 90 mg in a 7.5% glucose solution for subarachnoid anaesthesia (Laboratorios Palex SA, Barcelona, Spain) over a period of 10 s. The patient was awake during the spinal anaesthetic. There were no signs of pain or paresthesiae on insertion of the needle or during injection of the local anaesthetic and the patient was placed immediately in the supine decubitus position. Anaesthesia reached the T8 level and surgery lasted 35 min with no complications. Seventy minutes after injection of the anaesthetic, after signs of sensory and motor recovery had been observed, the patient was transferred to the ward. Thirty-one hours after surgery he complained of continuous burning pain perceived symmetrically on both sides from the hips to the popliteal fossa (L3–4). The pain was unaffected by change in position and no loss of strength or sensation was evident. There was no neck stiffness and no fever. The pain was not relieved by non-steroidal anti-inflammatory drugs (NSAID), heat pads or benzodiazepine compounds. The pain clinic was consulted and bilateral neuropathic pain, possibly related to subarachnoid anaesthesia, was diagnosed. Treatment with carbamazepine and metamizole, and a dose of amitriptyline at night, produced obvious improvement. This regimen was replaced by clonazepam and metamizole 24 h later, when dysarthria appeared. After 2 days on this treatment, and 4 days after anaesthesia, the pain disappeared completely and the patient was discharged 6 days after surgery with no sequelae.

Discussion

Neurological complications of subarachnoid anaesthesia are rare but potentially serious and at times difficult to diagnose. There are various causes, including direct neural damage by puncture, infections, haematomas, ischaemia caused by hypotension or other factors such as vasoconstriction or root distension [6]. The usual local anaesthetics and doses used for spinal anaesthesia are considered safe and have rarely been blamed for complications. Major neurological problems are rare; in 65000 operations with intradural anaesthesia, Kane [7] found only 16 such events, ranging from cases of mononeuropathy to lesions of the lumbar plexus. However, in another prospective study of 10098 cases of spinal anaesthesia in which the authors recorded minor neurological complications [8], pain identical to that seen after general anaesthesia in the lower extremities was found in 1% of cases.

Correspondence to R.R.-C.

The safety of hyperbaric 5% lignocaine began to be questioned by Schneider and colleagues [4], who reported four cases of pain in the lower extremities (L5–S1) after spinal anaesthesia with single doses through a needle. The authors emphasized the possibility that the lithotomy position may have played a role, given that in dissections in that position the L5–S1 roots were lower and distended. A similar case was reported recently by Sjöström and Blåss [5].

Our case differed from the previous reported cases of transient lumbosacral neuropathy in that the patient was placed in the supine decubitus position, the affected roots were L3 and L4, and the pain appeared later and was relieved by antidepressants and anticonvulsants. The symmetrical nature of the pain and the lack of pain or paraesthesiae during the procedure suggests that no damage was caused by the needle. There was no hypotension or hypoxia that might have led to medullary ischaemia and the anaesthetic did not contain adrenaline. Chemical contamination was highly unlikely as we used disposable equipment and strict aseptic procedures. A single injection of hyperbaric 5% lignocaine was administered at the recommended dose for subarachnoid anaesthesia [6]. Moreover, a 22-gauge needle was used, and therefore overdose or poor distribution because of slow injection seems unlikely to have caused the complication. Our patient's pain was at the L3 and L4 dermatomes but, in all previously reported cases, patients were placed in the lithotomy position and L5 and S1 were always affected. We do not know what role the supine decubitus position or other factors may have played in producing the highly unusual location of our patient's lesion.

In nine of 11 cases of cauda equina syndrome described in the literature and in six cases of transient lumbosacral neuropathy, including the one described here, the only agent clearly implicated is hyperbaric 5% lignocaine, although these complications have been observed in animal studies after subarachnoid anaesthesia with 2-chloroprocaine and bupivacaine in clinical concentrations [9, 10]. In another study in rats, sensory deficit lasted longer in the group receiving 5% lignocaine in 7.5% glucose than in groups receiving 0.75% bupivacaine in 8.25% glucose, 5% amethocaine with 5% glucose or saline solution [11]. Similarly, in the same experimental model, it was shown that the presence of 7.5% glucose did not affect the ability of 5% lignocaine to produce sensory deficits [12].

The possibility of developing minor, transient neuropathy after subarachnoid anaesthesia should not be underestimated, given that the responsibility for follow-up and treatment of pain belongs to the anaesthetist. Pain therapy was different in all cases; three of the patients were relieved by NSAID, another by pethidine and one patient refused to take analgesics [4, 5]. Our patient also received NSAID but he was not relieved of pain until antidepressants and anticonvulsants were added. We believe that the clinical picture described here occurs more often than the literature suggests, but, as the condition unfolds 24 h after surgery, it often remains undiagnosed.

We believe that the use of hyperbaric 5% lignocaine for subarachnoid anaesthesia is not risk-free when given in a single dose through a large-calibre needle or when a position other than lithotomy is used. We conclude that its clinical use should be questioned and further studies should be performed.

Pulsed saline lavage causing venous air embolism in a patient with Paget's disease

C. A. SIDES

Summary

Pulsed saline lavage is used to prepare bony surfaces during joint replacement surgery. A patient is described in whom a venous air embolism occurred as a result of a combination of the increased vascularity of bone seen in Paget's disease and possible air entrainment in the lavage equipment. (*Br. J. Anaesth.* 1996; **76**: 330–331)

Key words

Complications, embolism. Embolism, air. Complications, Paget's disease.

Case report

A 71-yr-old man presented for a left cemented Furlong hip replacement to replace an arthritic hip joint. He also suffered from Paget's disease (osteitis deformans) involving the shaft of his femur and mild chronic obstructive airways disease (COAD). Physical examination was unremarkable except for some basal crepitations consistent with his COAD.

Spinal anaesthesia was produced with 0.5 % heavy bupivacaine 3 ml at the L2–3 interspace with a 22-gauge Whitacre needle after preloading with 0.9 % saline 500 ml. Oxygen was supplied via nasal cannulae at 2 litre min^{-1} while the patient listened to music via headphones.

Monitoring included non-invasive arterial pressure, electrocardiography, pulse oximetry and verbal contact. Surgery performed in the supine position proceeded uneventfully for the first 100 min, including reaming and cementation of the acetabular component of the joint replacement.

Surgical preparation included use of a Stryker Ortholav pulsed lavage system to irrigate and clean the bony surfaces before cementation. The lavage tip was inserted deep into the femoral shaft such that the outer suction channel was in direct contact with the perimeter of the canal. During femoral lavage the patient complained of feeling unwell with the sudden onset of dyspnoea and coughing. This was associated with a reduction in systolic arterial pressure from approximately 125 to 65 mm Hg, heart rate decreased to 65 beat min^{-1} after a brief tachycardia of 115 beat min^{-1} and peripheral arterial oxygen saturation decreased from 95 % to 88 %. A provisional diagnosis of venous air embolism (VAE) was made and treatment consisted of i.v. morphine and ephedrine and changing his nasal cannulae to a face mask and 100 % oxygen. The nature of the operation precluded turning the patient into the classic left lateral position. His cardiorespiratory variables improved to allow cementation and completion of the operation.

Postoperative recovery was uneventful with no evidence of either myocardial, pulmonary or cerebral sequelae.

Discussion

Embolization during hip surgery, of air, surgical debris or cement, particularly during impaction of the femoral component, is well recognized and may occur in up to 30 % of cases [1]. Lavaging the bone and venting the shaft help to minimize these risks. Pulsed lavage uses a peristaltic pump to force saline through connecting tubing and then through a coaxial lavage cannula, the inner tube of which has four side holes at the tip to provide a spray action. The saline and debris are aspirated through the outer tube which is set slightly proximal to the tip and connected to a normal theatre suction apparatus. The Ortholav pump is capable of generating up to 4.7 Barr and a flow of 900 ml min^{-1}. The lavage system operates regardless of the efficiency of the suction apparatus which can be reduced by the presence of large pieces of debris in the tubing.

Normal use of the pulsed lavage may have occluded the stem of the femur and any air trapped distally would have been forced into the femur. A similar event is thought to have occurred during pulsed irrigation of a perineal lesion in a patient with an open pelvic fracture in which trapped air was forced into the venous circulation with subsequent cardiovascular collapse [2]. In the case described here, the volume of air involved would be unlikely to have produced clinical symptoms. The second possible cause related to the lavage system itself. During lavage the saline bag was changed and activation of the machine at this time entrained air into the tubing which was then forced into the femur. During normal use this would not cause problems as the air would be either aspirated into the tubing or vented to the atmosphere but in the presence of a tight seal between the lavage cannula and the femoral canal and an inadequate aspiration system, this could lead to high pressures of air in the femoral shaft with subsequent embolization. The

possibility of air being entrained in the tubing was demonstrated after operation and confirmed by the manufacturers. Rapid recovery would be consistent with an isolated event. A similar episode has been described during dental implant surgery when inadvertent injection of a mixture of air and water, passing through the hollow dental drill and directly into the mandible, caused death in three patients [3]. A VAE has been reported when injecting air into a femoral bone cyst during an attempt to aspirate it [4], so the increased vascularity seen in Paget's disease may have made such absorption more likely.

VAE is associated classically with anaesthetized patients undergoing neurosurgical procedures in the sitting position and diagnosis is based on end-tidal carbon dioxide measurements or precordial Doppler monitoring. In this case the latter was not available and the first sign was the patient complaining of breathlessness. The fact that the patient was under central neural block and not receiving nitrous oxide which, in anaesthetic concentrations, increases bubble size by between 200 % and 400 %, probably contributed to the fortunate outcome. Central venous cannulation is not used routinely but might have been helpful to aspirate any atrial collection of air.

The use of pulsed lavage systems is not universal and it is thought that there are about 120 units in use in the UK of which approximately 50 % are supplied by Stryker. The potential for significant VAE during the use of pulsed saline lavage should be remembered, especially in patients who may be at a higher risk of developing this complication, such as those suffering from Paget's disease. Care should be taken to ensure that air is not entrained in the lavage tubing and the aspiration system is functioning efficiently.

CORRESPONDENCE

Inadvertent infusion of glucose saline into the extradural space

Sir,—A 10-yr-old girl with scoliosis underwent corrective surgery during general anaesthesia combined with a continuous thoracic extradural. During surgery she received extradural fentanyl 4 μg ml^{-1} which was continued after operation. Anaesthesia and surgery were uneventful. After operation the extradural infusion was set at 2–6 ml h^{-1} and she had satisfactory pain control. On the third day after operation the patient started complaining of inadequate analgesia. The extradural fentanyl syringe was infusing at 6 ml h^{-1}, as ordered. In addition, a three-way tap was connected to the extradural infusion set adjacent to the extradural filter. The third limb of the three-way tap was connected to the infusion of glucose saline (0.9 % NaCl and 225 % glucose with potassium chloride 20 mmol) 21 ml h^{-1}. The glucose saline infusion which was intended for i.v. infusion had been in progress for at least 1 h. The extradural was discontinued immediately. The patient had no sensory or motor symptoms and daily assessment of the patient for up to 2 weeks after the incident showed no evidence of neurological deficit. Her subsequent course was uneventful and she was discharged from hospital 3 weeks later.

This report illustrates yet another potential hazard of providing postoperative analgesia via infusion of opioids or opioids into the extradural space. The incidence emphasizes the necessity that nurses caring for extradural infusions be adequately trained, and that the responsible physicians visit these patients routinely to supervise this aspect of care.

There have been previous reports of substances other than those intended being infused into the extradural space [1, 2]. However, I could not find any other reports involving inclusion of a three-way tap to the extradural infusion set.

Cardiac arrest at induction of anaesthesia for Caesarean section

Sir,—I wish to comment on the case report of a cardiac arrest at induction of anaesthesia for Caesarean section by McIndoe, Hammond and Babington [1]. They ascribed the cardiac arrest to peripartum cardiomyopathy and dismissed an anaphylactic reaction as unlikely.

There are reasons to suggest that an anaphylactic reaction was a likely cause of the patient's cardiac arrest instead of peripartum cardiomyopathy. The patient had no symptoms or signs of cardiac disease before induction of anaesthesia, which is unusual in cases of peripartum cardiomyopathy. The cardiac arrest occurred at induction of anaesthesia with drugs known to precipitate anaphylaxis, and responded to treatment for asystolic cardiac arrest and anaphylaxis, which included adrenaline by bolus and then infusion. The arrhythmias noted (including bradycardia unresponsive to atropine) are recognized manifestations of anaphylaxis [2].

Initial intensive care assessment revealed few cardiovascular abnormalities but the case report described progressive development of symptoms, signs and imaging features of cardiac failure. Profound, reversible myocardial contractile depression attributed to anaphylaxis has been reported in two patients by Raper and Fisher [3]. One patient had been anaesthetized with thiopentone and alcuronium and the other had received a bee sting. Both required intra-aortic counterpulsation balloon pumping and inotropic support for several days. The extent of cardiac dysfunction was documented with pulmonary artery catheter monitoring, echocardiography and radionuclide ventriculography. Raper and Fisher attributed their patients' myocardial contractile depression directly to anaphylaxis. They pointed out that it can also be associated with hypotension, hypoxaemia and acidosis which often accompanies anaphylaxis, especially in patients with underlying cardiac disease.

It may be important for this woman's future anaesthetic and obstetric management if anaphylaxis is regarded as a possible cause for her cardiac arrest and subsequent clinical course.

3. Raper RF, Fisher MMcD. Profound reversible myocardial depression after anaphylaxis. *Lancet* 1988; 1: 386–388.

Sir,—We thank Dr Wilson for his letter regarding our recent case report on a cardiac arrest occurring at induction of anaesthesia for an emergency Caesarean section [1]. It can be difficult to differentiate between minor signs and symptoms of cardiac dysfunction in the latter stages of pregnancy and less than 10 % of patients with peripartum cardiomyopathy present before delivery. The distinction between anaphylactoid and anaphylactic reactions to anaesthetic agents depends on whether there is documented previous exposure to the agent. This distinction is becoming somewhat blurred and they may have similar pathophysiology. In this case the patient had previously been exposed to both thiopentone and suxamethonium. There was no family history or known sensitivity to anaesthetic agents.

Severe anaphylactic–anaphylactoid reactions to anaesthetic drugs are uncommon [2]. The clinical picture is usually one of hypotension, bronchospasm, acute urticarial skin rashes and varying degrees of cardiovascular instability, including brady-dysrhythmias. Myocardial dysfunction, although reported, is rare in patients without underlying disease [3, 4].

The timing of events in this case strongly suggested an anaphylactic–anaphylactoid response to agents used at induction, that is suxamethonium, thiopentone or i.v. ranitidine (given 20 min before induction). Therefore, the patient was treated initially for anaphylaxis following the Wessex Regional Anaphylaxis Procedure [5], with appropriate serum and urine specimens obtained for subsequent analysis. However, further review of the patient alerted our suspicions to the possibility of a primary myocardial problem rather than a drug reaction. Notably there was complete absence of any cutaneous or pulmonary signs of systemic histamine release. Cardiac failure occurred 6 h after the primary event. Myocardial dysfunction was documented by echocardiography when the patient was transferred to the care of the regional cardiology centre who confirmed the clinical suspicion of peripartum cardiomyopathy.

Subsequent analysis of serial samples obtained at the time of the event and at regular intervals over the hours after presentation (according to the Wessex Anaphylaxis Procedure) showed a negative tryptase test, negative RAST (radioallergosorbent test) to suxamethonium, normal IgE concentrations and normal urine methyl histamine concentrations. Collectively, these results do not support the argument that this patient suffered an anaphylactic–anaphylactoid reaction as there was no objective evidence of mast cell degranulation and histamine release.

In the light of serological data available, the consensus of opinion from the anaesthetist, cardiologist and immunologist involved with this case was a diagnosis of peripartum cardiomyopathy.

Day-case cataract surgery

Sir,—Every day thousands of elderly patients are operated on as day-cases during general anaesthesia. Why is it only in ophthalmology departments that the only alternatives considered are inpatient surgery with general anaesthesia or day-case surgery with local anaesthesia [1]. This opinion was continued by Whitehead [2] in reply to the article of Moffatt and Cullen [1]. If the patient is suitable for day-case surgery, the mode of anaesthetic is irrelevant and can be left to patient preference. A short general anaesthetic for eye surgery is not traumatic or physiologically disturbing and will hardly delay discharge. Please do not encourage this continued attitude which excludes this large group from routine day-case surgery under general anaesthesia.

2. Whitehead PN. General anaesthesia for day-care cataract surgery. *British Journal of Anaesthesia* 1995; **75**: 252–253.

Sir,—We support Whitehead's 6 months' experience with a local anaesthetic management regimen for day-case cataract surgery [1].

Since 1984, regional–local anaesthetic techniques have been used for more than 39500 cataract extraction–lens implantation procedures at the Gimbel Eye Centre, Calgary [2] with postoperative discharge within 1 h. An additional advantage of these techniques, especially for diabetic patients, is that patients may continue with their normal diet before operation on the day of surgery [3]. General anaesthesia was used in 0.025 % of all cases; three adults in whom the indications were allergy to eye drops, severe coarse head tremor and mental handicap, and 93 children. None of the patients required admission to hospital. During the same period in Foothills Hospital, Calgary, regional–local anaesthesia was used in 99 % of 11000 adults, the remaining 1 % undergoing general anaesthesia, usually for patient preference.

During this time, there were three deaths in more than 50000 cases. One hospital patient, an obese 75-yr-old woman, suffered sudden cardiovascular collapse 20 min after retrobulbar block. Unlike patients in whom brain stem anaesthesia occurs [4], she could not be resuscitated. Pulmonary embolism was suspected because the patient had fallen 3 days earlier and bruised her leg. However, permission for autopsy was refused. Two elderly patients who had undergone regional anaesthesia at the Gimbel Eye Centre died after operation from acute myocardial infarction, one at 48 h and the other at 5 days. Although we have no data for a comparable group during general anaesthesia, we believe that this mortality rate is not unexpected, considering the physical status of many elderly cataract patients who suffer from concomitant systemic disease.

Effects of propofol on rabbit mesenteric arteries and veins

Sir,—I believe there are some problems with the article of Kamitani and colleagues [1]. First, there appears to be a mistake in the results section concerning the effects of propofol on noradrenaline-induced contraction, which states "...propofol 3×10^{-6} mol litre^{-1} significantly dilated the mesenteric artery without endothelium." This does not agree with figure 1, and I would suggest that what was meant was that propofol 3×10^{-5} mol litre^{-1} significantly constricted the mesenteric artery without endothelium. This would agree with the summary.

Similarly, in the section concerning the effect of propofol on K$^+$-induced contraction, the authors state "... in concentrations of 3×10^{-6} to 3×10^{-5} mol litre^{-1}, propofol significantly dilated the denuded mesenteric arteries ...". This does not agree with figure 2 which suggests that certainly no dilatation, but perhaps a small amount of contraction occurred.

In their final sentence the authors concluded that this study "suggested that vasoconstriction of noradrenaline-induced arterial contraction by propofol was caused by the inhibition of EDRF from the endothelium". This cannot be the whole story as constriction was maximal in arteries where there was no endothelium, and therefore no EDRF (nitric oxide) to inhibit. This study certainly adds support to the previous suggestion, cited by the authors [2], that propofol may inhibit the synthesis or action of EDRF. However, it seems more likely that the vasoconstricting action of very low concentrations of propofol in this model was caused by a direct action of propofol on the arterial smooth muscle cells. The fact that the vasoconstriction was less in intact than in denuded arteries supports the contention that EDRF might in fact oppose the vasoconstricting effect of propofol.

N. Stratford
Sir Humphry Davy Department of Anaesthesia
Bristol Royal Infirmary
Bristol

1. Kamitani K, Yamazaki M, Yukitaka M, Ito Y, Momose Y. Effects of propofol on isolated rabbit mesenteric arteries and veins. *British Journal of Anaesthesia* 1995; **75**: 457–461.
2. Park WK, Lynch C, Johns RA. Effects of propofol and thiopental in isolated rat aorta and pulmonary artery. *Anesthesiology* 1992; **77**: 956–963.

Sir,—I appreciate the letter by Dr Stratford which relates to our article.

We agree with Dr Stratford that there were several errors in our article and we regret these errors. In the results section, 3×10^{-6} mol litre^{-1} is apparently a typographical error, and should read 3×10^{-5} mol litre^{-1}. Also, the word "dilated" as he pointed out, should read "constricted". Therefore, we should state that: "propofol *3×10^{-5} mol litre^{-1}* significantly *constricted* the mesenteric artery without endothelium" in the noradrenaline-induced contraction section, and "in concentrations of 3×10^{-6} to 3×10^{-5} mol litre^{-1}, propofol significantly *constricted* the denuded mesenteric arteries" in the K$^+$-induced contraction section. As Dr Stratford suggested, the vasoconstricting action of low concentrations of propofol is likely to be caused by a direct action of propofol on arterial smooth cells.

Thank you for the opportunity to correct these errors.

A pitfall in the use of the Altman nomogram for power estimation

Sir,—We wish to draw attention to a pitfall in using Altman's nomogram [1] (or any equivalent method) for deciding the number of patients that need to be included in a clinical trial to ensure that it has adequate power, that is adequate probability of detecting a clinically important difference between two treatments. We encountered the problem when conducting a parallel-group trial to see if piroxicam, given before operation, reduced postoperative consumption of morphine in adults undergoing tonsillectomy.

To enter the Altman nomogram it is necessary to determine the "standardized difference": the minimum clinically important difference in the effect of the two treatments divided by the standard deviation (SD) between patients. We decided that a one-third reduction in morphine use would be worthwhile and obtained an SD of morphine usage following piroxicam in hip replacement of 40% of the mean [2]. Therefore, assuming that this percentage SD would apply to our patients, we calculated a standardized difference of $33\%/40\% = 0.8$. The nomogram then predicted the need for a total of 50 patients for a power of 0.8 at $P = 0.05$.

When the study was completed, morphine use in the piroxicam group was indeed almost one-third less than in the control group, but the SD between patients in our groups was not 40% but 90%! Therefore it is not surprising that our result was not significant, even allowing for the lower power [3] of the Mann–Whitney test that was needed because of the very skew distribution.

The essential message is that, in seeking a relevant estimate of the SD from the literature, it is not sufficient (and perhaps not necessary) to find a study that has tested the effect of the same treatment; what is needed is a study in which the SD of the outcome variable is likely to be the same as in the new study.

For example, a recent comparison of ketorolac and acetaminophen during tonsillectomy [4] used postoperative consumption of morphine as an outcome variable and reported SD values of 110%. The circumstances were somewhat different from those in our study and so the implications are a little ambiguous. However, if we had possessed that information at the time, we would certainly have been more cautious in our planning.

We have had to present this argument in terms of percent SD because the data demanded it; but clearly the problem would be exactly the same where absolute SD values were relevant. The SD culled from the literature must be relevant to the circumstances of the new study.

Change in neostigmine ampoules

Sir,—We are extremely distressed by the decision of Roche (UK) to discontinue the production of Prostigmin ampoules (neostigmine 0.5 mg in 1 ml) and in particular with the method of withdrawal, with no prior warning or discussion. More and more paediatric patients are from the smaller end of the spectrum of weights, because of the successes of neonatal intensive care. Diluting drugs to the extent needed is both inherently dangerous and inaccurate for a drug with a precise dosage. A dilution of 1:10 of the adult 2.5-mg ampoule results in a suitable dose only for a child more than 5 kg in weight. At a time when risk management and patient safety are uppermost in our minds, decisions such as this by drug companies, made for presumably purely financial reasons, must be resisted strenuously by the profession.

Volume preloading, spinal anaesthesia and Caesarean section

Sir,—I was interested to read the editorial and article on the subject of volume preloading before spinal block for Caesarean section [1, 2].

The authors of the article demonstrated that administration of fluids in the form of 1000 ml of crystalloid solution had no influence on the incidence, severity or duration of hypotension after extradural block. They have now abandoned the routine of preloading before regional anaesthesia. Before this message is acted upon may I suggest that the findings do not justify the conclusions and commend to all the advantages of preloading, as supported in your editorial.

Spinal anaesthesia results in peripheral vasodilatation and reduced systemic vascular resistance with frequent hypotension, which may or may not be accompanied by a reduction in cardiac output. Measurement of arterial pressure during anaesthetic procedures is universal and indeed it is considered negligent not to do so. However it is a poor substitute for what we should be measuring, that is cardiac output or oxygen delivery. It is clear that measurement of cardiac output in every patient is impracticable but until non-invasive, reproducible and accurate cardiac output measurement is available, we have to content ourselves with measurement of arterial pressure. Arterial pressure does not equate with cardiac output and taken in isolation is fairly meaningless. Statistically there is a poor correlation between arterial pressure and cardiac output ($r = 0.2$), as has been demonstrated by Reinhart [3].

Sivarajan and colleagues [4] have clearly demonstrated that low arterial pressure, in response to peripheral vasodilatation, can be accompanied by either an increase or decrease in cardiac output. Arterial pressure alone is not sufficient to indicate the state of cardiac output. Lawson and colleagues [5] have demonstrated that the directional change in cardiac output after the onset of hypotension secondary to vasodilatation depends on the preoperative intravascular volume. Low circulating blood volumes when associated with hypotension are accompanied by a low cardiac output following peripheral vasodilatation. Conversely, when adequate preload is available, hypotension can also be achieved by peripheral vasodilatation but without a reduction in cardiac output.

The importance of preinduction circulating volume before peripheral vasodilatation has also been demonstrated by Boon and co-workers [6]. These authors showed that the cardiac output response to vasodilatation with sodium nitroprusside depended on the state of the circulating volume. Cardiac output decreased in association with hypotension accompanying vasodilatation when the dogs were hypovolaemic but not when the animals were normovolaemic.

My own experience of approximately 1000 induced hypotensive anaesthetics using peripheral vasodilators supports this view. Preloading patients with 1 litre of crystalloid solution before reduction in arterial pressure avoids the reduction in $P\mathrm{E}_{CO_2}$ normally indicative of a decrease in cardiac output. In the absence of cardiac output measurement or capnography, I would suggest caution before adopting the recommendations of this article. Until these studies have been repeated while cardiac output is measured we should continue to preload patients and be very circumspect in how we interpret the often misleading results of measuring arterial pressure in isolation.

Sir,—We read with interest the article by Jackson, Reid and Thorburn [1]. The results of their study on the apparent lack of efficacy of i.v. crystalloid hydration in preventing spinal-induced hypotension are difficult to interpret because they contradict routine clinical practice. We wish to comment on several points.

The authors used ephedrine 47.5 mg (mean) which appears to be higher than that used routinely to treat hypotension. Hauch and co-workers [2] used ephedrine i.v., as necessary, to treat hypotension after spinal anaesthesia and their average requirement was 18.8 mg. However, Hall and co-workers [3] used a combination of an initial bolus followed by an infusion to treat hypotension and their mean dose was 59 mg. In this study, prophylactic ephedrine 60 mg in Hartmann's solution 500 ml was administered via an ordinary infusion set. The high dose of ephedrine used may have been a result of manual adjustment of the infusion, or it is possible that rapid tachyphylaxis to ephedrine may have developed because of the method of administration.

Apgar score and biochemical variables such as umbilical pH measurements are not sensitive indicators of changes in utero-placental perfusion and may reflect only an early and crude assessment of global neonatal activity which can be affected by many other variables occurring at the time of delivery [4]. However, Ramin and co-workers [5] demonstrated significant fetal acidaemia after prophylactic infusions of ephedrine in spite of preloading. Neurobehavioural score [6], a sensitive indicator of fetal well-being, could have been used to assess the effect of such a high dose of ephedrine. Jouppilla and co-workers [7] showed that after i.v. preload, placental blood flow is better maintained. Also, methods to assess placental perfusion such as umbilical artery Doppler velocimetry [8] are useful.

In the unpreloaded group, Hartmann's solution 200 ml was administered over 10 min. This appears to be excessive solely for maintaining the patency of a cannula. In addition, Hartmann's solution 400 ml, containing ephedrine, was infused after spinal injection. Another 400 ml of crystalloid was administered in parallel with the ephedrine infusion, after spinal injection. In total, the authors used more than 1 litre of crystalloid in this group. In our opinion, this is merely shifting i.v. hydration from the period before spinal injection to that after injection.

The authors treated hypotensive episodes with bolus doses of ephedrine and fluid. If fluid overload is such a concern (although a case of pulmonary oedema has not yet been reported in the literature after spinal anaesthesia), why did they not treat the hypotension with ephedrine alone?

We feel that on the basis of this trial alone, it is neither possible to conclude that preload is not essential nor is it possible to recommend a change in clinical practice. Moreover, the incidence of hypotensive episodes was similar in both preloaded and unpreloaded groups. The conclusion that may be drawn from this study is that neither preloading nor prophylactic ephedrine infusion alone prevents hypotension after spinal anaesthesia in obstetric patients. A sensible approach would be that which we practise in this institution, of using ephedrine early, and keeping preload and perioperative i.v. fluids to a minimum, compatible with both maternal and fetal well-being.

Sir,—We are gratified by the interest of Dr Lawes and Drs Mallick, Samaan and Braithwaite in our study, and thank you for the opportunity to reply.

We accept the risk of a type II error, but we selected our population carefully, as described in the text, to reduce patient variability. This inevitably had the consequence of introducing constraints such as the availability of adequate numbers of suitable patients within a reasonable period of time. The fact that the number and severity of hypotensive episodes were identical confirms the appropriateness of the study design.

We also agree that the relationship between cardiac output and arterial pressure is poor, and for this reason fetal acid–base balance assumes greater importance, and again, there was no difference between the two groups. There appears to be confusion between "hypovolaemia" and the effect of sympathetic block. Our patients were not hypovolaemic, indeed surgery was undertaken in the morning only, to ensure similar volaemic status among patients.

Preloading patients for elective Caesarean section and the prophylactic use or treatment with ephedrine by infusion is the standard regimen used in the prevention or management of maternal hypotension. There is, however, little agreement on what the optimum therapy is, and it was for this reason that the study was undertaken. It is also true that despite the variety of combinations of i.v. fluids and ephedrine in use, maternal hypotension after spinal anaesthesia remains a persistent problem. Many studies have demonstrated that neonatal acid–base balance is affected adversely by maternal hypotension, particularly if prolonged and is a readily obtained measure of adequate fetal perfusion. The role of neonatal neurobehavioural assessment in the presence or absence of maternal hypotension despite its use for over 21 years remains unproved, difficult to perform and requires resources which are not widely available.

Moving the rigid procedure of infusing i.v. fluid from the period before spinal injection to after injection represents the difference between prophylaxis against and treatment of the consequent sympathetic block, which was one of the aims of the study.

The combined use of preloading and infusion of ephedrine used in our study represents, in our view, standard practice. We agree with the final sentence of the letter of Drs Mallick, Samaan and Braithwaite, but what is the optimum dose of ephedrine, the volume of preload and the perioperative i.v. fluid load? We attempted to qualify the word "enough".

We have abandoned formal preloading, and our experience since adopting that approach has been reassuring, but we do infuse fluids when the block is developing and add ephedrine if hypotension develops.

Our article is now added to a growing number which question the validity of preloading in both pregnant and non-pregnant subjects with solutions which have an evanescent action. We await with interest the publication of larger studies. At present we are protecting our patients from infusion of large volumes of i.v. fluids, and the potential risk of delay in the emergency situation while waiting for a "suitable" preload volume to be infused. We too have had difficulty in coming to terms with changing the habits of a lifetime.

Accidental insertion of an extradural catheter

Sir,—We wish to support the authors Robbins, Fernando and Lim [1] on their finding that accidental insertion of an extradural catheter through a dural hole made by a spinal needle in the single space combined spinal extradural (CSE) technique may be more than a theoretical risk. Two similar cases have been reported briefly in the past [2] and we wish to report a similar case.

A 38-yr-old Asian woman was admitted for elective Caesarean section having required an emergency Caesarean section in a previous pregnancy. On arrival in the operating theatre, she received a preload of Hartmann's solution 1 litre and monitoring consisted of ECG, non-invasive arterial pressure and pulse oximetry.

A needle-through-needle CSE technique was carried out at L3–4 using a Portex 16-gauge Tuohy needle and a 24-gauge Sprotte needle. The procedure was carried out with the patient in the sitting position and the loss of resistance to air technique was used to identify the extradural space. The extradural space was located without difficulty and dural puncture with the Sprotte needle was confirmed by the sight of cerebral spinal fluid (CSF) at the hub of the spinal needle; 0.5% bupivacaine 2.5 ml with 8% glucose was injected. At the end of injection of the local anaesthetic, CSF could not be aspirated. After removal of the spinal needle and without rotating the Tuohy needle, an extradural catheter was threaded 3 cm into the extradural space. There was no CSF in the Tuohy needle and there was no resistance during the passage of the catheter. When the catheter had been secured, the patient was put onto her left side and turned onto her right side after 5 min. After 20 min, the patient had partial sensory block in her legs, no motor block and no sacral block. It was assumed at this stage that the spinal technique was unsuccessful. The decision was made to proceed to use the extradural catheter to provide extradural anaesthesia. After a negative aspiration test (aspiration through the filter after flushing the catheter with normal saline 1.5 ml to avoid an air lock [3]), a test dose of 2% lignocaine 3 ml with adrenaline 1:200000 was injected through the extradural catheter. Within 5 min, the patient developed bilateral motor and sensory block from T4 to S5. Aspiration of the catheter was attempted again but this gave a negative test. However, when the filter was disconnected and aspiration attempted once more, there was free flow of CSF. Dextrostix indicated a positive test for glucose (11–17 mmol litre^{-1}). This could have been caused by earlier injection of bupivacaine with glucose. The patient's blood glucose was 7 mmol litre^{-1}. After operation the catheter was left *in situ* and when sensation returned, plain bupivacaine 2.5 ml was injected through the catheter. This provided immediate pain relief with motor and sensory block from T12 to S5. At this stage, CSF was again easily aspirated and confirmed by a positive test for glucose (11–17 mmol litre^{-1}), 3 h having elapsed since the original injection of bupivacaine with glucose.

We believe that the extradural catheter had been placed accidentally in the subarachnoid space after the initial dural puncture was made by the Sprotte needle. Failure of the spinal technique could have been caused by relocation of the spinal needle to be partially in the extradural and subarachnoid spaces. It is less clear how placement of the catheter into the subarachnoid space occurred. One explanation could be that the catheter may have entered the subarachnoid space through the hole made by the spinal needle, a theory suggested by Robbins, Fernando and Lim. This would imply a catheter with an external diameter of 1.1 mm entering through a hole made by a needle with an external diameter of 0.55 mm. The second explanation is that a hole in the dura could have been made by the Tuohy needle. This was unlikely as there was no CSF visible through the Tuohy needle at the time of insertion and the Tuohy needle was not rotated between introducing the spinal needle and threading the catheter. The third explanation is that the end of the Tuohy needle may have been in the subdural space and placement of the catheter perforated the arachnoid mater and entered the subarachnoid space. The distance of approximately 7 mm between the end of the Tuohy needle and the side opening of the Sprotte needle when CSF was sighted would question this theory. Therefore, there is no clear explanation as to how the catheter came to lie in the subarachnoid space.

We were pleased to find on subsequent follow-up that, as in the case of Robbins, Fernando and Lim, our patient did not develop a post-dural puncture headache.

This case and those reported previously [1, 2] highlight the need to give a test dose after a CSE technique in order to exclude intrathecal placement of the catheter. As shown in our case, a negative aspiration test through the filter does not always exclude a catheter in the subarachnoid space. The use of CSE in obstetric anaesthetic practice is increasing and anaesthetists need to be aware of potential problems which may occur as their use becomes more widespread.

Transoesophageal echocardiography in chest trauma

Sir,—Kennedy, Ireland and McConaghy [1] described a case of acute trauma, with death from uncontrollable bleeding from a thoracic source. They used transoesophageal echocardiography (TOE) to exclude pericardial effusion and diagnosed interatrial pathology. Unfortunately, they did not describe the equipment used, and it is therefore assumed that they used a single plane probe, presumably with no colour Doppler facility. The echocardiograms illustrated are presumably those taken before the initial laparotomy.

Both pictures in fact show marked echodense material anterior to the right atrium and right ventricle, consistent with (but not diagnostic of) clot and blood within the anterior aspect of the pericardial cavity. In addition, there is surprising bowing of the interatrial septum towards the left atrium, suggesting that the left atrial pressures were lower than the right (2–8 cm H_2O). In view of these, transthoracic echocardiography (TTE) would have been an essential additional assessment, despite its notorious difficulty in patients with an intubated trachea, as views of the anterior mediastinum are seen more clearly. In retrospect, it may be reasonable to assume that the right atrial pressures were not raised because the pericardium had already "opened", and blood in the posterior and lateral mediastinum had drained to the thorax.

With regard to the diagnosis of atrial septal rupture and haematoma on the echocardiographic evidence, many caveats need to be added. In the plane of examination of the four-chamber view, the interatrial septum is almost parallel to the ultrasound beam, and artefacts are not unusual. The standard biatrial view, where the interatrial septum is perpendicular to the beam is more reliable [2]. The superior echodense area is not seen consistently, and the inferior effect reported to be haematoma is in a frame where the gain controls have been set too high (the mitral valve leaflets are too bright).

The defect referred to as atrial septal rupture seems clear. However, the defect is quite small and no attempt has been made to quantify it. Even assuming Doppler was unavailable, microbubble contrast material is clearly seen in both illustrations in the right atrium, while none is seen, or commented on, in the left heart (admittedly both being systolic frames). The ease of interatrial shunting (requiring a Valsalva manoeuvre?), colour Doppler, atrial enlargement and clinical assessment of hypoxia (shunt) or pulmonary oedema would help to quantify the significance of the atrial septal defect. It is also of note that the area of the IVC tear, from the central tendon to the right atrium, can be seen transoesophageally with a more inferior and rightward probe position [2].

There is clear evidence of direct trauma to the chest (fractured left clavicle and bilateral pneumothoraces) and there is probably no need to invoke transmitted abdominal pressure as a means of damage. The combination of TOE and TTE, with clinical evidence of bilateral damage, may have suggested an exploratory midline sternotomy rather than thoracotomy. In summary, TOE is a useful emergency investigative tool, but TTE is complementary. In addition, adequate TOE assessment includes not only the diagnosis but an assessment of significance in its clinical setting.

2. Oka Y, Goldiner PL. *Transoesophageal Echocardiography*. Philadelphia: JB Lippincott & Co, 1992; 55, 237–250.

Sir,—Dr George raises some interesting and worthwhile points. The equipment used was a Toshiba single plane transoesophageal probe with colour Doppler and pulse wave Doppler facility. Transoesophageal echocardiography was carried out in the patient during laparotomy, the patient having presented to the emergency department shocked, with continuing intraperitoneal blood loss. The echodense material anterior to the right atrium and right ventricle may have been blood, but there were no changes to suggest tamponade. Transthoracic echocardiography is certainly a useful adjunct and should generally be performed before transoesophageal echocardiography in all patients, but it was not possible in this patient because of the circumstances of his admission and the haste with which he was transferred to the operating room.

The views presented were chosen because they showed most clearly rupture of the atrial septum. As in any transoesophageal study, additional views, including the standard biatrial view, were obtained, but these did not add specifically to the presentation.

No attempt was made to quantify the defect in the atrial septum; microbubble contrast material was not noted in the left heart. The patient's trachea was intubated and his lungs were ventilated. It is of course useful to do a Valsalva manoeuvre in a conscious patient in a stable condition, but in this case it was not possible.

We agree wholeheartedly that transthoracic echocardiography and transoesophageal echocardiography are complementary, both having specific strengths, adding to the information which may be obtained by either modality alone. There will, however, continue to be patients who, because of their unstable condition, require urgent surgery and in some patients, as in our patient, it will not be possible to perform transthoracic echocardiography.

BOOK REVIEWS

Anaesthesia and Critical Care Manual, 2nd Edn. A. J. Cunningham (editor). Published by the Royal College of Surgeons in Ireland. Pp. 244; illustrated. Price IR £15.00.

With the recognition that anaesthetists have an important role in undergraduate education, a second edition of this book has been produced as a basic guide for medical students and newly qualified doctors. It consists of five sections covering preoperative evaluation, intraoperative anaesthetic management, postoperative anaesthetic management, trauma and critical care, and specialized topics including chapters on pancreatitis and chronic pain management. In addition there is a short final section of multiple choice questions on the subjects covered. There is no index, although individual topics are relatively easy to find. Most of the 22 chapters are in the form of "lecture notes" and can be read in less than 15 min, some in considerably less time.

Being a multiauthor book, the chapters vary in style and content, and there is an impression that some may have been edited drastically to reduce the size of the book. Although the information is up to date and presented in a succinct fashion, many chapters can only be regarded as revision notes and barely cover the essentials. For example, the chapter on postoperative pain is three pages long. In contrast, other chapters are excellent synopses of topics undergraduates typically find difficult to understand, in particular the chapter on ARDS. Unfortunately, the text is riddled with spelling mistakes and typographical errors, which at best are annoying and at worst sometimes alter the meaning. There are also notable omissions, the ASA grading system is mentioned in the text, but it is not described. There are many illustrations and photographs but many are far too small to be useful, especially the radiographs. In conclusion, this book will be of little use to anaesthetists in training but may be of some use to medical students and newly qualified doctors as a revision aid.

A. Ogilvy

Anaesthesia and Intensive Care for Patients with Liver Disease. G. R. Park and Y. Kang (editors). Published by Butterworth–Heinemann, Oxford. Pp. 271; indexed; illustrated. Price £75.00.

At first sight this volume appears rather slim, but the 271 pages are densely packed with scientific and clinical information. The editors, recognized as leaders in this area on their respective sides of the Atlantic, have brought together 26 contributors from the UK and the USA. As would be expected, there is a degree of repetition but this does imply that many chapters can be read in isolation. However, I did find that a lack of cross-referencing and an inadequate index made consulting the book for a specific topic difficult.

The book is divided into four sections: assessment, pharmacology, anaesthetic considerations and intensive care. Chapters on paediatrics, acute liver failure and postoperative intensive care are particularly readable and practical. There are detailed and extremely helpful descriptions of liver function tests and coagulation.

Considerable pre-existing knowledge is required for a book such as this, but I did expect more detail on practical techniques, for example intracranial pressure monitoring.

Although the subject matter does not often lend itself to visual presentation, a lack of illustrations gives the text a rather monotonous and dry feel, especially as the print is small. The anatomy section especially would benefit from more illustrations.

These criticisms aside, this is an excellent and comprehensive account. The information is as current as the multiauthor textbook format allows. Although the examination candidate will find too much detail, the chapters I have highlighted provide a good review. The whole book should be available to all anaesthetists and intensivists, wherever they work, as they are increasingly called on to care for patients with liver disease.

I. Wilson

Principles and Practice Series: Respiratory Support. K. Sykes. Published by BMJ Publishing Group, London. Pp. 254; indexed; illustrated. Price £24.95.

This is a splendid little book. Although Keith Sykes complains that he is now a senior citizen with a bus pass, it is only by a lifetime's experience of his subject that so much knowledge can be presented in this concise format. His apologies that brevity has resulted in a didactic style are also unnecessary, as common sense does not need to be long winded.

Within 254 pages there is a broad outline of all aspects of respiratory support from the historical perspective through physiology, mechanics of ventilator modes, artificial airways, clinical indications and general care to advice about sedation. The highlights for me are the 100 pages discussing the physiology and mechanical bases of respiratory support and the subsequent chapters on various means of controlling airway pressure. He makes it all seem simple and easy to understand. It is, however, fair to say that the length of the book implies that certain aspects are a little superficial; for example, ventilator technology is covered in 20 pages with one ventilator chosen to exemplify the important design features of modern machines. I would also have liked a little more about clinical conditions and indications for respiratory support and better integration of the section on choice of support mode for particular clinical conditions, but these caveats do not alter my positive overall impression of the book.

The book is well illustrated with clear line drawings, some of which are old friends from previous Sykes' publications. Each chapter is well referenced with references dating from 1543 to 1994! The text is nicely laid out and appears so crisp and straightforward that it is easy to underestimate just how much information is incorporated into its pages.

Although Keith Sykes has spent his working life deeply engrossed in respiratory physiology, there remains a welcome, honest cynicism about him, for example "there is unfortunately little evidence to indicate that the use of any of the special ventilatory modes has had any influence on mortality" and "if in doubt use a simple ventilator with controlled ventilation; it will probably do less harm in the long term"! I also bond with an author who writes "setting controls poses no problem to the computer literate younger generation but may initially prove time consuming for those used to more conventional control systems".

A recommended snip at £25.

P. G. M. Wallace

The ABC of Resuscitation, 3rd Edn. M. C. Colquhoun, A. J. Handley and T. R. Evans (editors). Published by BMJ Publishing Group, London. Pp. 88; indexed; illustrated. Price £7.95.

Five years after the second edition, this third edition has been completely revised and rewritten by members of the UK Resuscitation Council. There are now 20 chapters, four of which are new, and an extra 18 pages; the chapters on resuscitation in the accident and emergency department and on multiple injured patients have been deleted.

The successful format and style of the previous editions have been retained, with the addition of colour for the algorithms; many black and white photographs complement the text. Up-to-date references are now given at the end of most chapters and equipment manufacturers' addresses listed as appropriate.

The initial chapters cover resuscitation techniques using the European Resuscitation Council (ERC) 1992 guidelines. A new chapter details the management of peri-arrest arrhythmias and the role of the laryngeal mask in the airway at risk is discussed. Resuscitation of infants and children succinctly covers their basic and advanced life support according to 1994 ERC guidelines. There are chapters on resuscitation in pregnancy, at birth, near drowning and the risk of HIV and hepatitis.

The chapter on the ambulance service now includes audit data from the UK and demonstrates the great advances made in the past 5 years; this is followed by a discussion of the role of the general practitioner. There are three chapters on training, including the public, ALS courses, retention of skills and a comprehensive description of adult training manikins. (Alas, the floor space allocated for training areas does not appear to have increased!) The often thorny problems which may arise as the result of a resuscitation attempt are tackled in the chapter on ethics, which stresses the importance of a hospital policy and discusses other areas of concern such as legal aspects, infection hazards and the involvement of relatives. The concluding chapters on drugs and their delivery and cardiac pacing complement the penultimate one on post-resuscitation care.

Editorial mistakes are few but include the 1998 maternal mortality figures, THAN instead of THAM, meq and not mmols, the infant bag valve device without the oxygen reservoir and an obsolescent semi-automatic advisory defibrillator. Although the references are recent, it is a pity that the second edition's further reading section with its many important historic references has been omitted. I find it difficult to reconcile the statement that "cricothyrotomy is contraindicated in children under 12 years of age" with the 1993 ATLS and 1994 PALS teaching, which are in accord with the advice given in the second edition.

This is a very readable book which will appeal to everybody involved in resuscitation, whether at beginner or instructor level, in addition to inspiring an interest in the subject in new readers. The core chapters are carefully structured and develop the most recent ERC guidelines, with the others covering special situations in great detail. There is sufficient information to satisfy the needs of undergraduate and most postgraduate examinations. Armed with this manual, everyone will be able to resuscitate more confidently and competently.

T. M. O'Carroll

ERRATUM

British Journal of Anaesthesia 1995; 75: 588–592

p. 589. In the second paragraph, line 15 should read "This technique is sensitive to 1–2 pg using a *25-μl* sample [13, 14]. A *25-μl* plasma sample is used in the enzyme reaction" and not *25-ml*, as appears in the article.

EDITORIAL I

Remifentanil—an opioid for the 21st century

Remifentanil is a fentanyl derivative with an ester linkage (3-[4-methoxycarbonyl-4-[(1-oxopropyl) phenylamino]-1-piperidine] propanoic acid, methyl ester). It is a pure μ agonist [1] and the rapid breakdown of the ester linkage by non-specific tissue and plasma esterases is responsible for its unique characteristics. Considerable work is underway investigating this new opioid but, as yet, few data are available in the literature. However, these data enable an initial assessment of the properties of remifentanil and its potential use in anaesthesia.

The speed of onset of action of remifentanil is similar to that of alfentanil [2]. In patients undergoing elective inpatient surgery, the volume of distribution at steady state was 25–40 litre, total clearance 4.2–5 litre min^{-1} and terminal $T_{\frac{1}{2}}$ 10–21 min. Clearance was not affected significantly by body weight, sex or age [3], and it is likely to be independent of renal or hepatic function [4–6]. Furthermore, remifentanil is a poor substrate for butyrylcholinesterases (pseudocholinesterases) *in vitro* and clearance should be unaffected by cholinesterase deficiency or administration of anticholinesterases [data on file, Glaxo].

The main metabolic product of ester hydrolysis is a carboxylic acid derivative (GI90291) which is excreted by the kidneys (elimination half-life 88–137 min [3]). Although elimination of GI90291 is delayed in renal failure [6], significant pharmacological effects are unlikely as its potency relative to remifentanil is only 0.1–0.3%.

At present, remifentanil is formulated in glycine, an inhibitory neurotransmitter. Consequently, spinal or extradural administration is not recommended and there are no data on administration of remifentanil by these routes.

Rapid biotransformation to minimally active metabolites should be associated with a short, predictable duration of action with no accumulation of effect on repeated dosing or with continuous infusion. The available data suggest that remifentanil behaves in this way. Because of its pharmacokinetics, similar properties were expected of alfentanil [7]. However, clinical experience has shown that prolonged infusion of alfentanil may be associated with prolonged recovery time. It is now appreciated that the offset of clinical effect is not simply a function of the half-life, particularly in multicompartmental systems. It may be affected by rate of equilibration between plasma and effector site, method of administration (e.g. continuous infusion, intermittent boluses) and duration of infusion [8, 9]. Hughes, Glass and Jacobs [10] proposed the use of context-sensitive half-time ($T_{\frac{1}{2}\text{context}}$) and defined this as the time for the plasma concentration to decrease by 50% after terminating an i.v. infusion designed to maintain a constant plasma concentration. Context refers to duration of infusion. They demonstrated that context-sensitive half-times of commonly used i.v. anaesthetic agents and opioids could differ markedly from elimination half-lives and were dependent on duration of infusion.

In contrast, because of the unique metabolism of remifentanil, its $T_{\frac{1}{2}\text{context}}$ should be rapid and relatively independent of the duration of infusion. This has been confirmed by *in vivo* studies. Remifentanil $T_{\frac{1}{2}\text{context}}$ was 3.1 min after a 3-h infusion (at a rate sufficient to depress minute ventilation by 40–70%) with a time to pharmacodynamic recovery, as determined by minute ventilation, of 5.8 min. In comparison, the times for alfentanil were 44 and 34.2 min, respectively [11]. In another study, remifentanil and alfentanil were infused i.v. at rates of 0.05 $\mu\text{g kg}^{-1}\,\text{min}^{-1}$ and 0.5 $\mu\text{g kg}^{-1}\,\text{min}^{-1}$, respectively, for 4 h. These infusion rates resulted in a similar degree of respiratory depression. On termination of the infusions, ventilation recovered in 8 min after remifentanil and 61 min after alfentanil [12].

It has been confirmed that the effects of remifentanil are antagonized by naloxone [13]. Its potency is similar to that of fentanyl, and 15–30 times that of alfentanil [14, 15]. The effects of remifentanil on arterial pressure and heart rate after bolus administration of various doses of remifentanil (2–30 $\mu\text{g kg}^{-1}$) have been investigated 10 min after induction of anaesthesia with etomidate and midazolam and maintenance with nitrous oxide–isoflurane–vecuronium [16]. Mean reductions in arterial pressure and heart rate in excess of 20% were found, the effects being unrelated to dose. I.v. administration of remifentanil resulting in hypotension was not associated with histamine release. More detailed haemodynamic investigations are awaited, as are comparisons with other opioids.

The EEG effects of remifentanil are similar to those of other opioids in humans [17] and dogs [18]. Remifentanil infusion is associated with an age-related reduction in the MAC of isoflurane in humans [19]. For example, at age 40 yr, MAC was reduced by 50% at a target remifentanil plasma concentration of 1.2 ng ml^{-1}. The effect was more marked in older patients. A ceiling effect was observed at 32 ng ml^{-1} and MAC was not reduced to zero.

Inevitably, nausea and vomiting may be consequences of remifentanil administration. However, because of its rapid clearance, the incidence of these side effects may prove to be less compared with other opioids in some situations. For example, in patients undergoing unilateral eye surgery under local anaesthesia and i.v. fentanyl or remifentanil, the incidence of nausea after surgery in the recovery room was 54 % and 8 %, respectively [20]. However, it is necessary for these provisional data to be confirmed in larger studies.

The characteristics of a remifentanil–nitrous oxide anaesthetic technique have been reported in the US literature [21–23]. Haemodynamic stability and rapid recovery were described. However, such techniques, without the use of an i.v. or volatile anaesthetic drug, are unlikely to gain widespread acceptance in the UK because of concerns regarding awareness. Studies are underway investigating the use of remifentanil infusions with propofol or volatile anaesthesia but few data are available at present.

Rapid i.v. infusion of large doses of potent opioids are associated with an incidence of muscle rigidity and remifentanil is no exception. In a comparative study of remifentanil 1-μg kg^{-1} bolus followed by 0.5 μg kg^{-1} min^{-1} and alfentanil 25-μg kg^{-1} bolus followed by 1 μg kg^{-1} min^{-1}, the incidence of muscle rigidity was 8 % and 5 %, respectively [data on file, Glaxo]. The majority of cases were described as mild or moderate (i.e. manual ventilation was still possible). As with other opioids, the incidence and severity are dependent on dose and rate of administration.

Based on the evidence so far presented, it may be that remifentanil will be used widely because of its predictability and easily reversible effects. However, its use also presents the anaesthetist with a significant challenge. If remifentanil is the only opioid administered during anaesthesia, it must be remembered that shortly after the end of the procedure, the patient will not benefit from opioid-based analgesia. This problem must be addressed if remifentanil is to be used for procedures associated with significant postoperative pain. Such techniques may include reducing the infusion rate of remifentanil to analgesic doses (which should be relatively simple), immediate administration of longer acting opioids as the effects of remifentanil begin to fade and increased awareness of the possibilities of local anaesthesia.

Such a short-acting and predictable opioid has not been available before to anaesthetists and it is difficult to predict precisely where its niche will lie. However, it has numerous potential applications ranging from short stimulating procedures to prolonged infusions where rapid recovery is required. Possibilities abound, not only in anaesthesia but in intensive care medicine. Overall, it represents a unique alternative to the currently available opioids and the results of further studies are awaited with interest.

EDITORIAL II

Voltage-sensitive Ca^{2+} channels and anaesthesia

Many investigators have examined the effects of anaesthetic agents on voltage-sensitive and ligand-gated ion channels and on the regulation of neurotransmitter release in the search for a target site(s) for anaesthesia. However, a single common target remains elusive. Recently, the $GABA_A$ receptor has been championed as a target for all (excluding ketamine) anaesthetic agents. Indeed, several studies have demonstrated that isoflurane exhibits modest but significant stereoselectivity at $GABA_A$ receptors [1–3] but not at L-type voltage-sensitive Ca^{2+} channels [4]. Nevertheless, it is clear that calcium ions (Ca^{2+}) have an important role to play in the mechanism of anaesthesia as this divalent cation contributes to the regulation of neuronal excitability and neurotransmitter release through at least three different types (L, N, P) of voltage-sensitive Ca^{2+} channels [5]. In this editorial we evaluate the evidence in support of voltage-sensitive Ca^{2+} channels as a target for anaesthetic agents.

Since, Nowycky, Fox and Tsien [6] described neuronal voltage-sensitive Ca^{2+}channels as (transient) T-type, (long lasting) L-type and (neither T nor L) N-type, (at least) six different classes of Ca^{2+} channels have now been defined (T, L, N, P, Q and R), both electrophysiologically and pharmacologically [7] (table 1).

T-type

T-type channels are found on both central and peripheral neurones in addition to non-neuronal tissues such as muscle and secretory cells, and are involved in the regulation of burst firing and repetitive discharges as pacemakers in neurones [8]. Although no selective T-channel antagonists have been described, this channel can be distinguished electrophysiologically as the current is low-voltage-activated. This channel may be affected in stroke and seizure as anti-ischaemic agents [8] and anticonvulsants [9, 10] have been reported to reduce the T-current. Electrophysiologically the T-current is inhibited by volatile anaesthetics in a dose-dependent manner [11–13]; pentobarbitone 0.5 mmol $litre^{-1}$ is ineffective [14]. Propofol also depresses this current at high concentrations (0.3 mmol $litre^{-1}$), although an effect at clinically relevant doses has not been demonstrated [15]. It is not clear if the T-channel is involved in the mechanism of general anaesthesia.

L-type

L-type Ca^{2+} channels are located predominantly on neuronal cell bodies, may modify neurotransmitter release under certain circumstances and are involved in some aspects of gene expression [8]. So-called "classic" Ca^{2+} channel blockers inhibit the L-channel; these include dihydropyridines (e.g. nifedipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem). Electrophysiologically the L-current is sensitive to dihydropyridines. Several *in vivo* studies have suggested that the L-channel may contribute to the mechanism of anaesthesia, although blood–brain barrier permeability of L-channel blockers is controversial. Maze, Mason and Kates [16] found a decrease in the MAC for halothane with verapamil in dogs. Moreover, Dolin and Little showed that L-channel blockers such as verapamil, flunarizine and nitrendipine augmented the general anaesthetic potencies of ethanol and pentobarbitone [17], and of benzodiazepines [18], while Bay K8644, an L-channel activator, reduced the anaesthetic actions of benzodiazepines. Consistent with these data, Horvàth, Szikszay and Benedek [19] reported that verapamil enhanced the duration of the hypnotic–anaesthetic action of dexmedetomidine, and that in contrast, Bay K8644 significantly increased the time to onset of hypnosis and attenuated anaesthetic action. In addition to the many reports indicating that both volatile and i.v. anaesthetic agents depress the L-current in skeletal and cardiac muscle [20–23], several reports may be found describing anaesthetic action on L-currents in neuronal tissue; for example depression of neuronal L-channel activity (measured electrophysiologically) [13–15] and binding of L-channel ligands [4, 24].

N-type

N-channels are distributed widely in the nervous system and endocrine cells, and are localized especially on presynaptic terminals of peripheral neurones [25]. N:L channel density ratio in the rat brain is 10–80:1 [26]. N-channels play an important role in the control of neurotransmitter release [27] and are sensitive to ω-conotoxins [8]. To date, there have been few anaesthetic studies performed with N-channels, although volatile anaesthetics have been reported to inhibit unseparated high-voltage-activated currents [11, 12] and dihydropyridine-insensitive neurotransmitter release [25]. Clinically

Table 1 Classification of voltage-sensitive Ca^{2+} channels and the interaction of anaesthetic agents. LVA = Low-voltage activated; HVA = high-voltage activated; NA = not available; DHPs = dihydropyridines; ϖ-CgTx = ϖ-conotoxin GVIA. ↓ = sensitive, → = insensitive, ? = controversial

	Ca^{2+} channel			
	T	L	N	P
Conductance (pS)	8	25	13	14
Activation	LVA	HVA	HVA	HVA
Specific inhibitor	NA	DHPs	ϖ-CgTx	ϖ-Aga-IVA
Volatile anaesthetics	↓	↓	↓	→?
I.v. anaesthetics	↓?	↓	↓	→?

relevant concentrations of isoflurane [13], propofol [15] and several barbiturates [28] significantly depress this current.

P-type

This channel was described initially in cerebellar Purkinje cells [29] and is distributed widely in the central nervous system and surprisingly may constitute about 80% of the voltage-sensitive Ca^{2+} channels in mammalian nerve terminals. This channel may also mediate central synaptic transmission [30–32]. In a study by Hall, Lieb and Franks [33] the P-channel in rat cerebellar Purkinje neurones was found to be insensitive to both volatile and i.v. anaesthetic agents. However, Study [13] showed in rat hippocampal pyramidal neurones that 2.5% isoflurane significantly reduced an ω-conotoxin with nitrendipine-resistant current, which probably includes the P-current.

In the article by Study [13], 2.5% isoflurane was found to inhibit the N- and L-channel peak current by 34 ± 8 and 38 ± 7%, respectively. N- and L-channel sustained currents were decreased by 84 ± 6 and 93 ± 15%, respectively. Gundersen, Umbach and Swartz [28] also reported that pentobarbitone 1 mmol $litre^{-1}$ inhibited 70% of the steady state barium current while the peak inward current was diminished by about 40% through ω-conotoxin-sensitive and dihydropyridine-resistant Ca^{2+} channels in *Xenopus* oocytes. However, the relative importance of peak or sustained current inhibition in the mechanism of anaesthesia needs clarification.

An important consideration in studies of the mechanism of action of anaesthetic agents relates to what is a clinically relevant concentration. In addition, some authors report that brain i.v. anaesthetic concentrations may be significantly different from their plasma concentrations. Archer and colleagues [34] found that the brain concentration of thiopentone was 25% of that of the plasma concentration in rats. In contrast, Shyr and colleagues [35] reported that the brain concentration of propofol after 30 min of i.v. infusion was 7.8 times higher than its plasma concentration in rats.

Another point for consideration is whether or not the *in vitro* IC_{50} value for inhibition of Ca^{2+} channel activity by anaesthetic agents should be related directly to IC_{50} concentrations for general anaesthesia [36], for example MAC. It should be borne in mind that MAC is a whole body-population determination, and it is not known how this relates to 50% inhibition of an electrophysiological–biochemical event in an isolated preparation. Moreover, it is inconceivable that the central nervous system (or cardiovascular system) could withstand a 50% reduction in Ca^{2+} channel activity. Should we be estimating IC_{25}? This seems reasonable as several studies suggest that clinically relevant concentrations of anaesthetics may inhibit release of neurotransmitter with only a 20–30% reduction in Ca^{2+} entry [25, 36, 37].

While a good case can be made for voltage-sensitive Ca^{2+} channels as a target site for anaesthetic agents, further research in this area is essential. Important issues that will need to be addressed using combined physiological, pharmacological and molecular biology approaches include: Is their selectivity in the action of anaesthetic agents for different channel classes? Where on the channel do anaesthetic agents interact? Is there a role for Q, R and other voltage-sensitive Ca^{2+} channels in anaesthesia? Only when this information is gathered will it be possible to fully confirm or exclude a role for this important class of ion channels in the process of anaesthesia.

CLINICAL INVESTIGATIONS

Prediction of postoperative nausea and vomiting using a logistic regression model†

C. C. Toner, C. J. Broomhead, I. H. Littlejohn, G. S. Samra, J. G. Powney,
M. G. A. Palazzo, S. J. W. Evans and L. Strunin

Summary

In a previous study, logistic regression analysis was used to determine the association of independent fixed patient factors with the incidence of postoperative nausea and vomiting (PONV). Female sex, previous history of PONV, use of postoperative opioids, previous history of motion sickness and an interaction between male sex and previous history of PONV were combined in an equation from which risk of PONV could be estimated. The present study was designed to test this equation in a group of patients with wide selection criteria. Data on 400 patients were collected in relation to pre-, per- and postoperative factors which may influence the incidence of PONV. The equation was used to predict PONV, and actual outcome was compared with that predicted. The overall incidence of PONV was 36%. The equation predicted an overall probability of PONV of 27.4%. If the model was used to define individual patients as predicted to have or not to have PONV, it was correct only 71% of the time. However, there was good agreement between the actual incidences of PONV and those predicted among the 16 risk groups created by the model. (*Br. J. Anaesth.* 1996; **76**: 347–351)

Key words
Vomiting, nausea. Vomiting, incidence. Vomiting, nausea, anaesthetic factors. Vomiting, nausea, surgical factors. Model, logistic regression.

The incidence of postoperative nausea and vomiting (PONV) has remained nearly constant over the past 30 yr (20–30%) despite considerable changes in other aspects of anaesthetic practice [1–11]. Until recently, PONV was considered a relatively unimportant postoperative complication, but the growing emphasis on day-case surgery has focused attention on complications which might delay discharge. Development of effective antiemetic therapy has been hampered by the multifactorial nature of PONV. This has presented considerable difficulty to investigators in ensuring adequate standardization of study groups for the risk of PONV. A more rigorous approach to the study of PONV requires quantification of the relative contribution of individual patient, surgical and anaesthetic factors in its aetiology. This information could be used to ensure that drug treated and control groups of patients are at equal risk of PONV before operation. It would also allow comparison of observed and predicted outcomes between studies.

In a preliminary study, Palazzo and Evans [12] developed a model for prediction of postoperative emesis in patients undergoing minor orthopaedic surgery. Variable factors (i.e. those that may be modified by the anaesthetist) were controlled. This involved a standardized anaesthetic technique of induction with thiopentone 4 mg kg^{-1} followed by spontaneous ventilation with a mixture of 2% enflurane and 65% nitrous oxide in oxygen. Fixed patient factors were allowed to be distributed freely (e.g. age, weight, sex). Logistic regression analysis was used to determine the association of independent fixed patient factors with the incidence of PONV. The fixed patient factors of sex, history of previous emesis, postoperative opioids and an interaction between sex and previous emetic history were identified as significant independent variables. Motion sickness had a weak association which did not reach statistical significance but was retained in the model on the basis that this was probably a result of the small number of patients. These factors were expressed in a logistic regression equation from which the risk of postoperative emesis for an individual patient could be calculated before operation. The object of the current study was to test the predictive value of this model in a heterogeneous patient group where surgical and anaesthetic factors were subject to considerable variation.

Patients and methods

After obtaining approval from the hospital Ethics Committee, we studied 400 patients (274 female). Twenty-one patients were undergoing elective ENT

Table 1 Factors recorded in the questionnaire

Preoperative	Peroperative	Postoperative
Name	Duration of fast	Position in post-anaesthetic recovery room
Age	Anaesthetist	Time of first oral intake
Hospital no.	Surgeon	Opioid analgesia
ASA physical status score	Operation	Antiemetics
Ethnic origin	Duration of operation	Nausea or vomiting during first 24 h
Sex	Induction agent	
Previous anaesthetics	Neuromuscular blocker	
Previous postoperative nausea and vomiting	Opioid	
	Antiemetic	
History of motion sickness	Gases/vapours	
History of vertigo	Other drugs	
History of migraine headaches	Airway: use of tracheal tube, laryngeal mask airway, oropharyngeal airway, etc	
History of morning sickness		
History of starvation nausea		
Smoking	IPPV/SV	
Allergies	Antagonism of neuromuscular block	
Medication	I.v. fluids	
Medical problems	Lowest systolic arterial pressure	
	Lowest Sa_{O_2}	
	Highest E'_{CO_2}	

Table 2 Actual *vs* predicted PONV

	Actual non-vomiter	Actual vomiter	Total
Predicted non-vomiter	226	85	311
Predicted vomiter	31	58	89
Total	257 (64.2%)	143 (35.8%)	400 (100%)

surgery, 35 maxillofacial surgery, 49 orthopaedic surgery, 141 gynaecological surgery, 114 general surgery and 22 urological surgery. For 18 patients the surgical specialty was not recorded. Median age was 44 (range 17–91) yr and ASA status was I–III (I 63%; II 29%; III 8%). The patients were interviewed the night before surgery and 24 h after operation. A questionnaire was completed which included both fixed and variable patient factors which previous studies have suggested influence PONV (table 1) [13]. In this study, variable factors relating to the perioperative period were not controlled. Details from the intraoperative and early recovery periods were recorded by the patient's anaesthetist and recovery nurse. All patients were allowed opioid analgesics and antiemetics as required after operation. Twenty four hours later the patient was revisited by an investigator and episodes of PONV, time of first oral intake, and use of opioids and antiemetics were recorded. Postoperative emesis was defined as vomiting (an integrated reflex resulting in expulsion of gastric contents), retching (a non-productive vomit) or nausea (the sensation of wishing to vomit).

Multiple linear regression allows the prediction of a single dependent variable (outcome) from the values of other explanatory (predictor) variables. However, this approach is only suitable when the outcome variable is continuous (e.g. birth weight). When the outcome variable is binary, as in the present study, multiple logistic regression is used [14]. To avoid impossible values of the dependent variable, a logit transformation is performed. If P is the probability an individual will vomit, then $1-P$ is the probability they will not. The ratio $P/1-P$ is termed the odds and thus the log odds is

$$\text{logit}(P) = \ln(P/1-P)$$

The relative effects of the fixed patient factors identified by Palazzo and Evans [12] were summarized in the equation:

$$\text{log odds (of emesis)} = -5.03+2.24\ \text{(opioid analgesics)}+3.97\ \text{(previous emetic history)}+2.4\ \text{(sex)}+0.78\ \text{(motion sickness)}-3.2\ \text{(sex}\times\text{previous emetic history)}.$$

To calculate the predicted probability of postoperative emesis for each patient, the use of opioid analgesics in the first 24 h after operation, previous postoperative emetic history, previous history of motion sickness or female sex was coded as 1, while absence of a factor or male sex was coded as 0. For example, from this formula a male with a previous history of emesis, motion sickness and who also received opioids would have a log odds of emesis in the first 24 h after operation of 1.96. This results in a calculated probability of emesis of 0.876 or 87.6%. For calculating the risk of any group of patients, the individual patient probabilities should be summed and divided by the number of patients to provide a mean (SD). Each of the four factors used in this equation has just two possible values so that there are $2^4 = 16$ risk groups. Each group has a different predicted probability of PONV ranging from males with none of the risk factors with a predicted probability of PONV of 0.6%, to the group used as an example above with all of the risk factors for whom the predicted risk is 88%.

When predicting outcome for individuals, the logical cut-off is 50%. Those with a predicted probability of less than 50% become predicted non-vomiters and those with a predicted probability of 50% or greater predicted vomiters.

The association of the factors recorded in the questionnaire (table 1) with PONV was assessed in the current study group. Nominal data were explored initially by univariate analysis with contingency tables between vomiters and non-vomiters and continuous variables by logistic regression. The combined effects of all variables were then analysed by stepwise logistic regression. The statistical software used was STATA (Stata Inc. College Station, TX 77840, USA).

Results

Of the 400 patients included in the study, the model had an average predicted probability of PONV of 27.4%. The number who did have PONV was 143 (36%). When a 50% cut-off was used to predict which individuals would or would not have PONV, the model predicted that 89 (22%) would vomit (table 2). Of these, 58 did vomit giving the model a positive predictive value of 65%. A total of 311 patients were predicted not to vomit and this proved to be the case in 226, producing a negative predictive value of 73%. The overall correct prediction rate of the model was 71%. A total of 143 patients vomited and the model correctly predicted 58 of these, giving a sensitivity of 41%; 257 patients did not vomit and the model correctly predicted 226 of these, giving a specificity of 88%.

Table 3 shows the predicted and actual outcomes for each of the 16 risk groups generated by the model. In general, there was better agreement in the groups that were larger or at higher predicted risk of PONV. This became more apparent when the predicted percentage in each of the 16 groups was plotted against the actual percentage of PONV (fig. 1). In figure 1, the groups are shown as circles, the radius of which is proportional to the size of that group. The overall incidence of PONV was higher than that predicted and this is reflected in figure 1 where most of the circles lie just above the line that would represent perfect prediction by the model. The agreement between the observed and predicted rate of PONV was much greater than would be expected by chance (correlation weighted by group size = 0.89, $P < 0.005$).

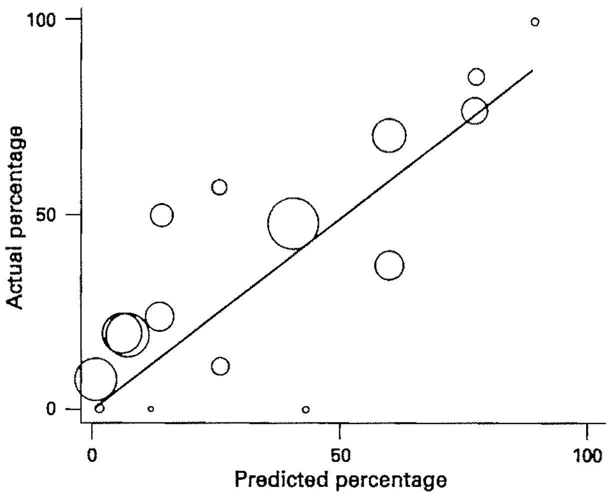

Figure 1 Actual *vs* predicted percentage of PONV. Each group is represented by a circle of radius proportional to the number of subjects in the group.

In this study, factors that were significantly more prevalent in vomiters than non-vomiters were female sex, previous history of postoperative emesis, increased duration of anaesthesia and use of the laryngeal mask airway, opioids or any neuromuscular blocking agent. Factors that were not significantly different for vomiters or non-vomiters were age, ASA status, ethnic origin, previous history of morning sickness, motion sickness, vertigo, migraine headache or starvation nausea, smoking, type of premedication, preoperative or intraoperative use of antiemetics, grade of anaesthetist, nature of surgery, induction agent, volatile agent, use of a tracheal tube, positive pressure ventilation, lowest recorded intraoperative systolic arterial pressure or arterial oxygen saturation, or highest end-tidal carbon dioxide. The combined effects of all variables were then analysed by stepwise logistic regression. Three factors were independent contributors to PONV. These were sex (odds ratio 2.9), previous emetic history (odds ratio 2.9) and opioid analgesics (odds ratio 3.7). All of these were highly statistically significant ($P < 0.0005$). As in the original study, motion

sickness narrowly failed to reach statistical significance.

Discussion

An effective model for estimation of the risk of PONV using fixed patient factors would be a potentially useful tool for future investigators in ensuring that their study groups are balanced. The model described in this article had been developed intentionally in a restricted patient group that received a standardized anaesthetic technique to maximize the relative effects of fixed patient factors [12]. The current study tested this model in a larger and heterogeneous patient group.

There are different approaches which may be used to assess the performance of the model. If individual patients are defined as predicted vomiters or non-vomiters, then a predicted risk of 50% is a logical cut-off. This resulted in a correct prediction rate of 71% which although reasonable, is in fact not substantially greater than chance alone would allow. While this indicates that the model is not outstanding at predicting outcomes for individual patients, this approach tends to underestimate the predictive value of the model because it does not demonstrate how it performs within groups of patients. Many patients will have a predicted risk of PONV of the order of 50%. With a 50%, yes/no cut-off, the model will often appear wrong because by definition the patient has only a 50:50 chance of PONV. If the model is effective at determining risk of PONV, then the actual incidence of PONV in groups of patients with the same combination of factors will be similar to that predicted. This was indeed the case in the larger groups of patients and those at greater risk of PONV (fig. 1, table 3). This is seen best in the 22 patients predicted to have a 76% risk of PONV and among whom the actual incidence was 77%. The agreement between the observed and predicted rate of PONV was much greater than would be expected by chance (correlation weighted by group size = 0.89, $P < 0.005$). Thus the model is effective at estimating the risk of PONV in groups of patients and particularly those at high risk of PONV. This is exactly the group that investigators should be targeting, both because they represent a group most likely to benefit from improved antiemetic therapy and because use of a high-risk group increases the power of the study.

The study also confirmed that among fixed patient factors, female sex, use of opioids and previous history of PONV contribute disproportionately to subsequent episodes. Of these, previous history of PONV is often overlooked in study standardization. The contribution of female sex as a fixed patient factor in PONV has been noted by many previous investigators, although restricted to adult, premenopausal women. This predisposition extends to types of surgery not normally associated with a high incidence of PONV (e.g. orthopaedic surgery [9]). These observations suggest that fluctuations in female sex hormones during the menstrual cycle play an important role and indeed the greatest incidence of PONV in adult females occurs during the third and fourth week of the menstrual cycle [15].

Nausea and vomiting are common side effects of perioperative opioids, irrespective of the route of administration. There is evidence that the emetic effects of opioids are mediated via opioid receptors in the area postrema, resulting in activation of the vomiting centre. It has also been speculated that by directly activating the vestibular system, opioids increase the sensitivity of the emetic reflex [16].

The association of previous history of PONV with subsequent episodes has received far less attention, although as long ago as 1964 Purkiss observed a three-fold increase in vomiting in the first 24 h in patients who had experienced previous postoperative vomiting [17]. It has been suggested that those individuals with previous PONV or motion sickness may have a well developed reflex arc for vomiting [18].

The impact of a significant improvement in antiemetic therapy would be considerable, particularly at a time when there is increasing emphasis on early hospital discharge. Unfortunately, the difficulties of adequately standardizing patient groups for this highly multifactorial complaint have limited the validity of much of the work in this area. This study confirms that in a large and heterogeneous patient group, female sex, use of opioids and previous history of PONV play a substantial part in determining subsequent episodes of PONV. A model based on these factors and motion sickness was not particularly effective when used to define patients simply as predicted to have or not to have PONV. However, in predicting the risk of PONV in groups of patients with various combinations of risk factors, the model was effective, with good agreement between observed and predicted incidences. This was most significant in larger groups or those at greater risk of PONV.

Metabolic and hormonal responses to induced hypotension for middle ear surgery

M. C. NEWTON, G. D. CHADD, B. O'DONOGHUE, S. M. SAPSED-BYRNE AND G. M. HALL

Summary

We have investigated in 30 patients the metabolic and hormonal responses to middle ear surgery using induced hypotension to a mean arterial pressure of 55 mm Hg. A standardized anaesthetic technique of propranolol, thiopentone–vecuronium–isoflurane was used in all patients and hypotension induced with sodium nitroprusside, trimetaphan camsylate or additional isoflurane. All patients showed a classic stress response with an increase in circulating blood glucose, cortisol and growth hormone concentrations. Blood lactate and plasma uric acid concentrations changed little during operation, suggesting that tissue oxygenation was adequate. However, the former declined after operation, possibly as a result of the concomitant use of propranolol. There were no significant differences between the three hypotensive techniques in their effects on the hormonal and metabolic response, although the increase in blood glucose concentration in the trimetaphan group was obtunded. We conclude that induced hypotension for middle ear surgery induced an endocrine and metabolic response of small magnitude and short duration. (*Br. J. Anaesth.* 1996; **76**: 352–357)

Key words

Anaesthetic techniques, hypotensive. Metabolism, glucose. Hormones, glucocorticoid. Surgery, otolaryngological.

The classic endocrine and metabolic response to surgery is approximately proportional to the severity of the surgical trauma. For example, cardiac surgery results in large and sustained changes in catabolic hormone secretion with prolonged hyperglycaemia, whereas cataract extraction evokes only transient increases in circulating cortisol and glucose concentrations [1]. Hormonal responses to the use of induced hypotension for surgery have received considerable attention, but have been confined mostly to investigation of changes in sympathoadrenal activity and in the renin–angiotensin–aldosterone axis [2–4]. Although Engquist and colleagues examined the glucose and cortisol response to middle ear surgery in six patients, it is not clear if induced hypotension was used [5].

The aim of the present study was to compare the effects of three hypotensive regimens, isoflurane, sodium nitroprusside and trimetaphan camsylate, on the metabolic and endocrine responses to middle ear surgery conducted at a mean arterial pressure (MAP) of 55 mm Hg. The use of nitroprusside compared with trimetaphan is associated with an increase in sympathoadrenal activity [2] and would be expected to stimulate glucose and lipid metabolism. However, it is usual practice to administer a β adrenergic blocking drug to prevent reflex tachycardia after induced hypotension and it is not known if the use of such an agent may modify the metabolic response.

Patients and methods

After obtaining approval from the Ethics Committee of the Royal National Throat, Nose and Ear Hospital and written, informed consent, 30 ASA I patients undergoing middle ear surgery were allocated randomly to receive isoflurane, sodium nitroprusside or trimetaphan camsylate to induce hypotension.

Patients were premedicated with papaveretum 0.3 mg kg^{-1} and hyoscine 0.006 mg kg^{-1} i.m., approximately 1.5 h before induction of anaesthesia. On arrival in the anaesthetic room, a radial artery cannula was inserted for measurement of arterial pressure and a central vein catheterized for administration of fluids. Routine monitoring commenced. After a rest period of at least 10 min, a control arterial sample was collected for measurement of metabolite and hormone concentrations.

Propranolol was given slowly i.v. to a total dose of 0.05 mg kg^{-1}, or was discontinued if heart rate slowed to 50 beat min^{-1} or less (seven patients in each group received the total dose). Five minutes later anaesthesia was induced with thiopentone and tracheal intubation facilitated with vecuronium 0.1 mg kg^{-1}. The lungs were ventilated with isoflurane and 50 % nitrous oxide in oxygen and the end-tidal partial pressure of carbon dioxide was maintained at 3.5 kPa. The patient was transferred to theatre and positioned on the table with an 8°

Correspondence to G.M.H.

head-up tilt. Measurement of arterial pressure continued with the transducer placed at the mid-axillary line. Anaesthesia was maintained with isoflurane at an end-tidal concentration of 0.8%. Sodium chloride solution (0.9%) was infused i.v. at 5 ml kg^{-1} h^{-1} during surgery and at 3 ml kg^{-1} h^{-1} in the postoperative period.

Hypotension was induced before surgery with the aim of achieving and maintaining MAP at 55 mm Hg throughout surgery. Patients allocated to the isoflurane group received as much isoflurane as necessary to maintain this MAP. Patients in the remaining two groups continued with isoflurane at an end-tidal concentration of 0.8%. In the trimetaphan group, MAP was controlled with an infusion of trimetaphan camsylate (500 mg in 0.9% sodium chloride solution 490 ml) and the nitroprusside group by an infusion of sodium nitroprusside (50 mg in 5% glucose 2 ml and 0.9% sodium chloride solution 498 ml). The hypotensive drugs were given via a separate i.v. cannula. Any increase in MAP in response to surgical stimulation was treated by increasing the dose of the appropriate hypotensive agent. Neuromuscular block was maintained with an infusion of vecuronium.

Twenty and 40 min after the start of surgery, additional arterial samples were collected for measurement of hormone and metabolite concentrations. Towards the end of surgery the hypotensive agent was withdrawn to permit MAP to return to normal and haemostasis obtained. Papaveretum 0.2 mg kg^{-1} and prochlorperazine 0.15 mg kg^{-1} were given i.m. Residual neuromuscular block was antagonized by neostigmine and glycopyrronium. Haemodynamic monitoring was maintained for at least 2 h after completion of surgery and additional arterial samples collected 30, 60 and 120 min after normotension had been achieved. Glycopyrronium was given i.v. if heart rate was less than 50 beat min^{-1}.

METABOLITE AND HORMONE ANALYSIS

Blood glucose, lactate and pyruvate concentrations and plasma non-esterified fatty acid (NEFA) concentrations were determined enzymatically by standard methods [6]. Plasma uric acid values were measured colorimetrically using the enzyme uricase [7]. Serum cortisol, growth hormone (GH) and insulin concentrations were measured with sensitive and specific radioimmunoassays that have been described in detail previously [8]. The intra- and inter-assay coefficients of variation were 4.3% and 7.0% for cortisol, 8.2% and 10.0% for GH, and 6.6% and 9.5% for insulin, respectively. Packed cell volume (PCV) was measuring using the microcapillary method.

STATISTICAL ANALYSES

Parametric data are expressed as mean (SEM) and analysed using two-way analysis of variance (ANOVA), with Dunnett's test for within-group changes with respect to the control sample. Between-group changes were analysed by ANOVA. GH data were not normally distributed and therefore expressed as median (range). Within-group analysis was made with Friedman's two-way analysis of variance and between-group comparisons with the Kruskal–Wallis test. $P < 0.05$ was accepted as significant.

Results

Two of the 30 patients studied had abnormally increased fasting blood glucose concentrations and data from these patients were excluded. There were no significant differences between the three groups in age, sex distribution, body weight, body mass index, time of surgery, type of surgery, duration of preoperative starvation, dose of propranolol and duration of hypotension (table 1). The surgeons noted no difference in the quality of the operative field for the three hypotensive regimens and no patient showed any neurological sequelae.

ARTERIAL PRESSURE (fig. 1)

MAP decreased significantly in all three groups during surgery ($P < 0.01$) and after 40 min of surgery was 53, 55 and 55 mm Hg in the isoflurane, trimetaphan and nitroprusside groups, respectively. In the postoperative period, rebound hypertension did not occur and MAP was not significantly different from control values. There were no significant differences between the three groups.

METABOLITES

Blood glucose (fig. 2)

Significant increases in blood glucose concentration were found in the isoflurane group ($P < 0.05$, 20 and 40 min of surgery) and nitroprusside group ($P < 0.05$, 40 min of surgery, $P < 0.01$, 30 min recovery). In contrast, the small increase in blood glucose in the trimetaphan group (5.3–6.1 mmol $litre^{-1}$) failed to reach statistical significance. There were, however, no significant differences between the groups.

Blood lactate and pyruvate (table 2)

There was a small increase in lactate concentrations in all three groups with the onset of hypotension and surgery, but this change was not significant. In the postoperative period lactate concentrations declined and this change was significant in the isoflurane and trimetaphan groups ($P < 0.01$). There were no significant differences in lactate values between the three groups.

There were no significant changes in blood pyruvate concentrations within and between groups during the study.

Plasma NEFA (table 2)

Circulating NEFA concentrations decreased significantly in all three groups ($P < 0.01$, 20 min of surgery in the isoflurane and trimetaphan groups, and $P < 0.01$, 30 min recovery in the nitroprusside group). There were no significant differences between the three groups.

Table 1 Patient details (mean (SEM or range) or number)

	Group I (isoflurane) ($n = 9$)	Group II (trimetaphan) ($n = 9$)	Group III (SNP) ($n = 10$)
Age (yr)	43 (24–59)	39 (29–58)	32 (21–47)
Sex (M:F)	4:5	2:7	6:4
Body mass index (kg m^{-2})	22.6 (1.7)	23.7 (1.2)	24.0 (0.8)
Time of surgery (am:pm)	6:3	5:4	7:3

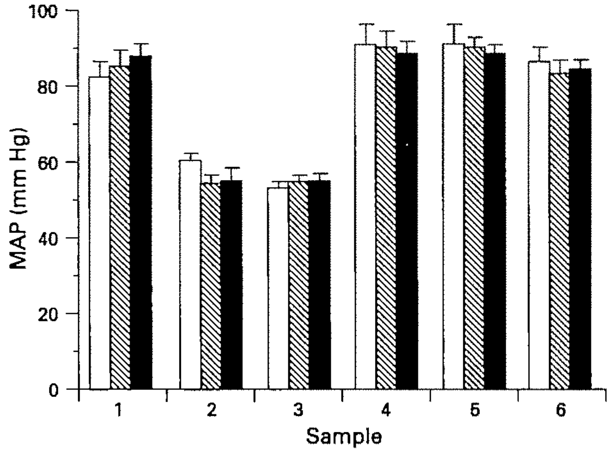

Figure 1 Mean (SEM) mean arterial pressure (MAP) in the isoflurane (□), trimetaphan (▨) and sodium nitroprusside (■) groups. Sample 1 = control, 2 = 20 min of surgery, 3 = 40 min of surgery, 4, 5 and 6 = 30, 60 and 120 min, respectively, after restoration of normal MAP.

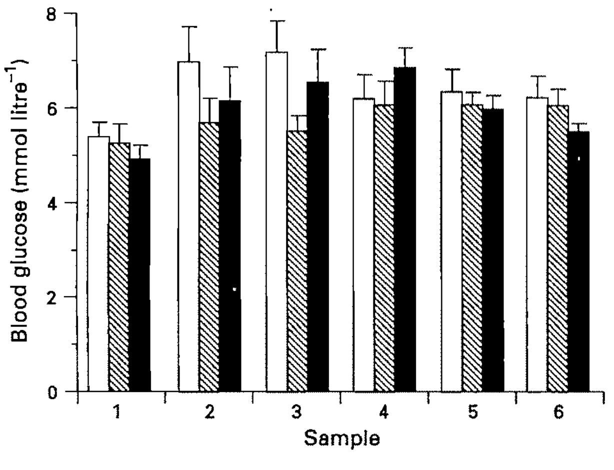

Figure 2 Mean (SEM) blood concentrations in the isoflurane (□), trimetaphan (▨) and sodium nitroprusside (■) groups. Sample 1 = control, 2 = 20 min of surgery, 3 = 40 min of surgery, 4, 5 and 6 = 30, 60 and 120 min, respectively, after restoration of normal MAP.

Plasma uric acid (table 2)

Uric acid values increased significantly after 40 min of surgery and 60 min recovery in the isoflurane group ($P < 0.05$), and after 60 min recovery in the trimetaphan group ($P < 0.05$). There were no significant differences between the three groups.

HORMONES

Serum cortisol (fig. 3)

Serum cortisol concentrations increased during surgery in all groups, but this change was significant only in the nitroprusside group ($P < 0.01$, 40 min of surgery). However, significant increases occurred in all three groups after 30 and 60 min recovery ($P < 0.05$ isoflurane and trimetaphan, $P < 0.01$ nitroprusside). There were no significant differences between the groups.

Serum GH (table 2)

GH concentration increased significantly in all groups after only 20 min of surgery ($P < 0.01$) and declined slowly in the postoperative period. There were no significant differences between the groups.

Serum insulin (table 2)

Insulin values decreased during surgery, but this change was significant only in the trimetaphan ($P < 0.05$, 20 and 40 min of surgery) and nitroprusside ($P < 0.01$, 20 min and $P < 0.05$, 40 min of surgery) groups. There were no significant differences in insulin values between the three groups.

Packed cell volume

PCV declined significantly in all three groups ($P < 0.05$ isoflurane, $P < 0.01$ trimetaphan, nitroprusside), but there were no significant differences between groups.

Discussion

All three groups of patients showed a typical metabolic and hormonal response to surgery with an increase in circulating glucose, cortisol and GH concentrations. The size and duration of the response were similar to that described in other forms of

Table 2 Mean (SEM) blood lactate and pyruvate concentrations (mmol litre^{-1}), plasma NEFA and uric acid concentrations (mmol litre^{-1}), and serum insulin values (mu litre^{-1}). Median (range) GH values (mu litre^{-1}). Significant differences from control: $*P < 0.05$, $**P < 0.01$

"low-stress" surgery such as ophthalmic and surface surgery [9]. However, there were no significant differences between the three techniques of induced hypotension in their effects on the metabolic and hormonal changes. This finding was unexpected, as the use of nitroprusside during hypotensive anaesthesia has been shown to increase markedly circulating catecholamines during surgery compared with administration of trimetaphan [2]. It is possible that the use of propranolol i.v. before induction of anaesthesia may have attenuated any difference in sympathoadrenal response. Khambatta and colleagues [10] found that premedication with propranolol decreased the release of catecholamines resulting from nitroprusside-induced hypotension. Nevertheless, the trimetaphan group was the only group that failed to show a significant increase in blood glucose concentrations, suggesting a diminished sympathetic response. A similar effect on the glucose response to surgery was found when pentolinium was used to induce hypotension for hip surgery [11].

The abrupt decline in plasma NEFA values was an unusual observation in studies of the metabolic response to surgery. It has also been found after i.v. infusion of the potent antilipolytic hormone, insulin [12]. In the present study, it is likely that propranolol resulted in the decrease in NEFA concentrations. The triacylglycerol lipase enzyme in adipose tissue is particularly sensitive to β adrenoceptor stimulation through the adenyl cyclase–cyclic AMP pathway [13].

Circulating lactate concentrations represent the balance between the production and utilization of a metabolite with a high turnover rate of approximately 1.2 mol day^{-1}. Alterations in blood concentration may be difficult to interpret, but it has been suggested that the typical lactate response to surgery at normal arterial pressure reflects an increase in sympathoadrenal activity [12]. This hyperlactataemia is associated with increased muscle glycogenolysis and hence lactate production, and is ameliorated by anaesthetic techniques, such as extradural analgesia and high-dose opioid anaesthesia, that are known to reduce the catecholamine response to surgery [6, 14]. With a decrease in MAP to 55 mm Hg during surgery in the present study, we expected an increase in circulating lactate as a result of cellular hypoxia, decreased hepatic and renal perfusion, or both. However, there was no significant change during surgery and a significant *decrease* in the postoperative period, possibly as a consequence of β adrenoceptor block.

Increase in circulating uric acid has been suggested as an indicator of cellular hypoxia [15]. Loss of adenosine triphosphate and its degradation to purine metabolites leads to an increase in uric acid production during hypotensive events [16]. Although we observed the occasional significant increase in plasma uric acid, all values remained within the normal range (< 0.4 mmol litre^{-1}). Our results suggest that, on the basis of two biochemical indices of hypoxia, lactate and urate, oxygen delivery is adequate during normovolaemic hypotension in healthy patients. However, regional hypoperfusion cannot be excluded.

There was a rapid increase in GH secretion to values seen commonly in major abdominal surgery [8]. In contrast, mean cortisol concentrations remained less than 500 nmol litre^{-1}. It is possible that the concomitant use of propranolol modified pituitary hormone secretion. In humans, it is clear that GH secretion is stimulated by α_2 adrenoceptors and inhibited by β adrenoceptors, but the effects of adrenergic drugs on ACTH secretion are ambiguous [17].

In conclusion, the use of induced hypotension for middle ear surgery is associated with a metabolic and endocrine response which is modified in part by the concomitant use of a β adrenoceptor blocking drug. Our study did not allow us to differentiate between the specific effects of surgical stimulation, induced hypotension and propranolol. We speculate that normovolaemic induced hypotension in healthy patients after propranolol may not trigger catabolic hormone secretion in the absence of surgery.

Influence of dose and timing of administration of morphine on postoperative pain and analgesic requirements

M. D. MANSFIELD, K. S. JAMES AND J. KINSELLA

Summary

In a randomized, double-blind study, we have investigated the effect of dose and timing of administration of morphine on postoperative pain and analgesic requirements in 60 patients undergoing hysterectomy, with or without salpingo-oophorectomy. Patients were allocated randomly to one of three groups: during standardized general anaesthesia, group post received morphine 0.15 mg kg^{-1} i.v. at peritoneal closure after hysterectomy; group pre-low received morphine 0.15 mg kg^{-1} on induction of anaesthesia; and group pre-high received morphine 0.3 mg kg^{-1} on induction of anaesthesia. Median postoperative morphine consumption (first 24 h) from a PCA system was 68 mg (group post), 56 mg (group pre-low) and 43 mg (group pre-high), and total perioperative morphine consumption (induction of anaesthesia to end of 24 h after surgery) was 77 mg (group post), 65 mg (group pre-low) and 63 mg (group pre-high). Pain scores (at rest and on movement) were similar in the three groups. A large dose of morphine 0.3 mg kg^{-1} i.v. on induction of anaesthesia significantly reduced postoperative PCA morphine requirements compared with the smaller dose (0.15 mg kg^{-1}) administered at induction or peritoneal closure, in patients undergoing hysterectomy, with or without salpingo-oophorectomy. (*Br. J. Anaesth.* 1996; **76**: 358–361)

Key words

Pain, postoperative. Analgesia, pre-emptive. Analgesics opioid, morphine. Surgery, gynaecological.

Management of pain after surgery is often inadequate but optimal pain relief is important as it may reduce postoperative complications and speed recovery and discharge of patients from hospital [1]. Increasing attention is now being focused on strategies to reduce, or even abolish, postoperative pain.

The objective of pre-emptive analgesia is to prevent reflex central neuronal hyperexcitability which occurs in the spinal cord in response to the afferent barrage from peripheral nociceptors after a noxious stimulus [2, 3]. When established, this central sensitization is difficult to suppress, and may make effective pain relief difficult or impossible to achieve [3]. Laboratory work in animals has shown that it is possible to reduce, or even block completely, spinal cord hyperactivity in response to a painful stimulus, using either local anaesthetics [4, 5] or opioids [6].

Various pre-emptive strategies have been used with opioid analgesics [7–11], local anaesthetics [7, 12–14] and *N*-methyl-D-aspartate receptor antagonists [15]. While some studies have supported a pre-emptive analgesic effect, others have been unable to demonstrate an effect clinically. We have attempted to confirm the findings of a study on patients undergoing hysterectomy [9] which showed a pre-emptive effect with morphine 10 mg administered on induction of anaesthesia, compared with giving the same dose at peritoneal closure. In addition, we investigated the difference between two doses of morphine, administered pre-emptively, on postoperative pain and analgesic requirements. An abstract of this work has been published previously [16].

Patients and methods

After obtaining local hospital Ethics Committee approval, we studied in a double-blind, randomized study, female patients, ASA I or II, aged 18–70 yr, weighing 45–100 kg, undergoing total abdominal hysterectomy, with or without salpingo-oophorectomy. The use of a patient-controlled analgesia system (PCAS) (Graseby Medical, Watford, UK), visual analogue scales and verbal rating scores was explained on the evening before surgery. All patients provided written informed consent, and recruitment continued until 60 evaluable patients had been included. We included only patients whose surgery was performed through a Pfannenstiel incision. Exclusion criteria were: patient request; any significant organ dysfunction; history of chronic pain; regular medication with any opioid or non-steroidal anti-inflammatory preparation; drug or alcohol abuse; or psychiatric disorder.

Before starting the study our hospital pharmacy prepared 75 pairs of ampoules, each ampoule

containing 10 ml of colourless solution. Each pair of ampoules was boxed and numbered consecutively, 1 to 75, and comprised one ampoule labelled "induction" and one labelled "closure". Pairs of ampoules contained one of three possible combinations: Group post: placebo in the induction ampoule, morphine 1.5 mg ml^{-1} in the closure ampoule; Group pre-low: morphine 1.5 mg ml^{-1} in the induction ampoule, placebo in the closure ampoule; and Group pre-high: morphine 3 mg ml^{-1} in the induction ampoule, placebo in the closure ampoule. All investigators were blinded as to the contents of the pairs of ampoules; the only codes to randomization were held in the pharmacy. Each patient was allocated randomly by being allocated the next pair of consecutively numbered ampoules.

All patients received premedication with temazepam 20 mg orally, approximately 90 min before operation. Routine monitoring comprised electrocardiography, non-invasive arterial pressure and pulse oximetry. Patients received a standardized general anaesthetic with induction of anaesthesia with propofol 2 ml kg^{-1}. Immediately after induction, patients received 0.1 mg kg^{-1} i.v. from the ampoule labelled "induction". Neuromuscular block was achieved with vecuronium 0.1 mg kg^{-1} and anaesthesia maintained with isoflurane and 66 % nitrous oxide in oxygen. After tracheal intubation, patients were transferred to the operating theatre and surgery commenced. After completion of the hysterectomy, as the surgeon started to close the peritoneum, all patients received 0.1 ml kg^{-1} i.v. from the ampoule labelled "closure". Surgery was completed and patients transferred to the recovery area.

During operation, patients received one of three analgesic regimens: group post: placebo on induction, morphine 0.15 mg kg^{-1} on closure; group pre-low: morphine 0.15 mg kg^{-1} on induction, placebo on closure; and group pre-high: morphine 0.3 mg kg^{-1} on induction, placebo on closure.

After operation patients were made comfortable in the recovery area with incremental i.v. morphine boluses, administered by one of the investigators, and then returned to the ward with a PCAS containing morphine (1-mg bolus with a 5-min lockout time and no background infusion). Twenty-four hours after surgery the PCAS was removed, as is routine practice in our institution, and patients then received diclofenac suppositories, 100 mg every 12 h. Co-proxamol was available for breakthrough pain in the second 24 h if required.

Pain was assessed at 1, 2, 4, 24 and 48 h after operation using visual analogue scales (VAS) for pain at rest and on movement (0 mm = no pain, 100 mm = worst pain ever had), and an eight-point verbal rating score for pain at rest (no pain = 0, just noticeable = 1, mild = 2, weak = 3, moderate = 4, strong = 5, severe = 6, excruciating = 7, same random word display shown to each patient). For pain on movement patients were asked to take a deep breath followed by a cough.

I.v. morphine administered by the investigator in the recovery room and total 24-h PCAS morphine consumption were recorded, together with analgesic consumption in the second 24 h after operation. Side effects, including nausea and vomiting, and requirements for antiemetic drugs were noted.

The Kruskal–Wallis test followed by the Mann–Whitney *U* test were used to compare total 24-h postoperative morphine consumption in the three groups. The area under the curve over time was calculated for visual analogue scores for pain intensity at rest and on coughing in individual patients. These summary data were then subjected to Kruskal–Wallis and Mann–Whitney *U* tests as appropriate [17]. The incidence of side effects was compared by chi-square test. Statistical analyses were performed in Minitab release 9.2. In all cases $P < 0.05$ was considered to indicate significance.

Results

Sixty-six patients were recruited in total and six were withdrawn because of: midline incision (two patients in group post), possible allergic reaction to morphine (one patient in group pre-high), severe anxiety altering the anaesthetic technique (one patient in group post) and further surgery within first 6 h after operation (two patients in group pre-high). The possible morphine allergy was evidenced by marked erythema of the face and neck with mild facial oedema, and was noted 4 h after operation. Patient-controlled analgesia was discontinued immediately and substituted with pethidine by intermittent i.m. bolus injection. The patient was not distressed, and the signs dissipated gradually over approximately 4 h.

Patient characteristics and type and duration of operation performed were similar in the three groups (table 1). The apparent difference in total postoperative morphine consumption (table 1) between the post and pre-low groups was not statistically significant. Patients in group pre-high used significantly less morphine in the first 24 h after surgery compared with patients in group post ($P = 0.0002$) and group pre-low ($P = 0.0016$). Total perioperative morphine consumption (i.e. allowing for additional i.v. morphine given during operation in group pre-high) was still significantly less in group pre-high compared with group post ($P = 0.018$) but not with group pre-low ($P = 0.27$). There were no differences between the groups in analgesic requirements in the second 24 h after operation.

Table 1 Patient characteristics, operation type and morphine use (median (interquartile range) or absolute values)

	Group		
	Post ($n = 18$)	Pre-low ($n = 22$)	Pre-high ($n = 20$)
Age (yr)	45 (41–48)	43 (39–49)	42 (36–46)
Weight (kg)	61 (55–65)	61 (55–68)	64 (60–70)
Duration of op. (min)	66 (46–83)	60 (49–67)	55 (51–78)
Hysterectomy	4	5	6
Hysterectomy + BSO	14	17	14
24-hour postoperative morphine use (mg)	68 (56–92)	56 (50–75)	43 (30–53)
Total perioperative morphine use (mg)	77 (65–102)	65 (60–84)	63 (51–73)

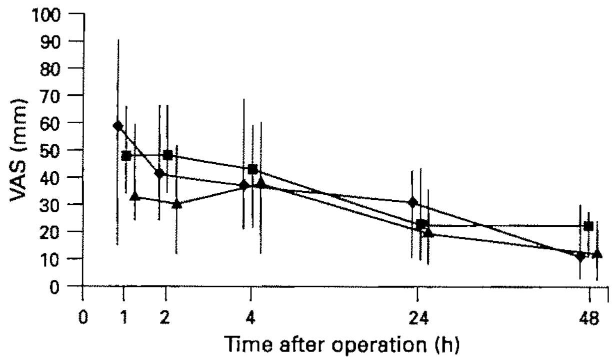

Figure 1 Visual analogue scores (VAS) for pain at rest (median, interquartile range) for group post (◆), group pre-low (■) and group pre-high (▲).

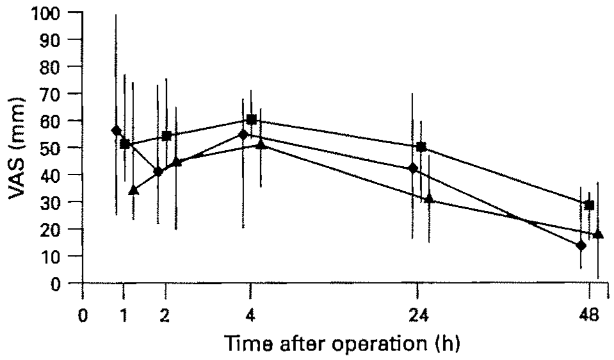

Figure 2 Visual analogue scores (VAS) for pain on coughing (median, interquartile range) for group post (◆), group pre-low (■) and group pre-high (▲).

Visual analogue scores for pain at rest and on movement are shown in figures 1 and 2. There were no significant differences between VAS at rest or on coughing, or verbal rating scores for pain at rest, in the three groups.

The incidences of nausea and vomiting were unacceptably high with 67% (group post), 59% (group pre-low) and 85% (group pre-high) of patients experiencing some degree of nausea or vomiting in the first 24 h after operation. Antiemetic therapy was required at least once by 44% (group post), 41% (group pre-low) and 60% (group pre-high) of patients. There were no significant differences in the incidence of nausea or emesis in the three groups.

Discussion

Only one study to date [9] has shown a clear pre-emptive analgesic effect using a simple opioid regimen. In that study it was found that morphine 10 mg i.v. significantly reduced postoperative PCA morphine consumption when administered on induction of anaesthesia compared with the same dose at the time of peritoneal closure. We have been unable to confirm this finding. In another study the same group [10] reached the conclusion that there was no clinical benefit in increasing the dose of pre-emptive analgesia. They also found that more sedation and an increased incidence of nausea and vomiting were sequelae of a larger dose of morphine.

Pre-emptive analgesia depends on reduction or prevention of central neuronal hyperexcitability (wind-up) which occurs in the spinal cord in response to peripheral nociceptive inputs. In the case of morphine analgesia, this is mediated by μ receptor stimulation. It has been shown that spinal cord wind-up begins almost immediately after a nociceptive stimulus [6], and thus any pre-emptive analgesic administered must be stimulating μ receptors at the commencement of such a stimulus. It is possible that a large dose of i.v. morphine may flood spinal opioid receptors more rapidly and to a greater extent than a smaller dose, and that this might result in a greater pre-emptive analgesic effect.

This possible explanation concurs with the findings in our study where group pre-high used 37% less morphine than group post, and 23% less than group pre-low in the first 24 h after operation. Obviously, group pre-high received twice as much intraoperative morphine as the two other groups but, even allowing for this, they still used 18% less morphine than group post in the perioperative period and this was statistically significant.

There was an unacceptably high incidence of nausea, vomiting, or both, in our study. Prochlorperazine was available to all patients after operation but we did not administer any intraoperative antiemetic. It should be stressed that even mild nausea was recorded, but 60% of patients in group pre-high required prochlorperazine at least once.

If the main purpose of intraoperative analgesia is to make patients more comfortable in the postoperative period (or permit an equal degree of comfort requiring less analgesic medication) then we conclude that a large dose of morphine administered on induction of anaesthesia significantly reduces postoperative morphine requirements from a PCA machine compared with a smaller dose given on induction of anaesthesia or at the time of abdominal closure.

Recovery after desflurane anaesthesia in the infant: comparison with isoflurane

A. R. WOLF, R. A. LAWSON, C. M. DRYDEN AND F. W. DAVIES

Summary

We have studied 20 infants, aged 2.5–8 weeks, undergoing general anaesthesia for pyloromyotomy with either desflurane or isoflurane. Patients were anaesthetized with equivalent 1 MAC values for age and agent. A blinded observer recorded times to breathing, swallowing, movement, extubation and side effects after discontinuation of the agent. Recovery times in the desflurane group were significantly shorter than in the isoflurane group. The times to swallowing, movement and extubation in the desflurane group were 3.89 (SD 2.4) min, 5.33 (4.95) min, 7.5 (4.53) min, respectively, and 8.82 (2.40) min, 10.73 (3.93) min, 13.45 (4.20) in the isoflurane group. In addition, postoperative apnoea was documented in the isoflurane group but not in those infants receiving desflurane. There was no laryngospasm after extubation in either group. We conclude that desflurane possesses useful characteristics for recovery conditions in the infant and may be particularly useful in the ex-premature infant prone to apnoea and ventilatory depression. (*Br. J. Anaesth.* 1996; **76**: 362–364)

Key words

Anaesthesia, paediatric. Anaesthetics volatile, isoflurane. Anaesthetics volatile, desflurane.

Neonates are susceptible to ventilatory depression after general anaesthesia [1] and this results partly from the residual effects of the volatile agent [2]. Isoflurane is often used in preference to halothane in the neonate because of its more rapid recovery characteristics. However, desflurane, a relatively new short-acting volatile agent, may confer further advantages with respect to quality of recovery. Desflurane has a blood:gas solubility of 0.42 [3] which should be associated with a more rapid recovery than isoflurane which has a blood:gas solubility of 1.4 [4]. Its use in paediatric anaesthesia has been limited by concerns about laryngospasm and breath-holding during inhalation induction. However, these effects are less relevant in neonates because the trachea is usually intubated on induction and the lungs ventilated during surgery. Taylor and Lerman demonstrated that these complications do not occur at extubation [5].

We therefore hypothesized that desflurane anaesthesia in infants would be associated with faster recovery than isoflurane even after a relatively short period of general anaesthesia and that there would be fewer postoperative ventilatory complications.

Patients and methods

After obtaining Ethics Committee approval and informed parental consent, we studied 20 patients undergoing pyloromyotomy. Patients were allocated randomly, using random number tables, to receive either isoflurane (even numbers) or desflurane (odd numbers) anaesthesia. No premedication was given and anaesthesia was induced with thiopentone 1.5 mg kg^{-1} and suxamethonium 1.5 mg kg^{-1} using a modified rapid sequence induction. Immediately after tracheal intubation, atracurium 0.5 mg kg^{-1} was administered and the lungs ventilated to normocapnia with 1 MAC of desflurane (9.16% neonates, 9.42% infants) [6] or isoflurane (1.6% neonates, 1.87% infants) [7] in 100% oxygen. Heart rate, arterial pressure and rectal temperature were recorded at 5-min intervals throughout the procedure. A normal value of 80 mm Hg for systolic arterial pressure in the awake neonate was used as baseline given the variability [8] and difficulty in recording accurate non-invasive readings in the unpremedicated awake infant. End-tidal concentrations of carbon dioxide and volatile agent were monitored (Datex Capnomac Ultima). End-tidal volatile agent was maintained at 1 MAC until surgery was finished, local anaesthetic had been infiltrated and residual neuromuscular block antagonized with neostigmine 40 μg kg^{-1} and atropine 20 μg kg^{-1}. The infant was then left undisturbed and normocapnia maintained with 100% oxygen. The onset of swallowing, breathing, movement and time to extubation were recorded by an observer blinded to the agent used. Perioperative and immediate postoperative ventilatory complications were documented. Breath-holding was defined as coughing and straining on the tracheal tube, and significant apnoea was regarded as a period of 15 s or more occurring after extubation.

Because of the relatively small sample size, numerical data of times recorded to breathing, swallowing, movement and extubation were analysed using the Mann–Whitney *U* test. Nominal data were analysed using the chi-square test with Yates' correction. $P < 0.05$ was considered significant.

Results

Both groups were comparable in age, weight and duration of surgery (table 1).

Figure 1 shows the times taken from discontinuation of the agent to breathing, swallowing, movement and extubation. The times taken to commence swallowing, movement and extubation were significantly shorter in the desflurane group ($P < 0.01$ for swallowing, $P < 0.05$ for movement and extubation).

Changes in heart rate and systolic arterial pressure are shown in figure 2. There was no statistical difference in heart rate or systolic arterial pressure between the two groups. Complications were recorded as a decrease in systolic pressure and breath-holding or apnoeic episodes. A decrease in systolic arterial pressure of more than 30 % from a normal neonatal awake value was regarded as clinically significant. Table 2 shows the number of patients in each group in which these complications occurred.

Discussion

We have observed that desflurane anaesthesia in the infant resulted in approximately twice the speed of recovery, in terms of breathing, swallowing, movement and extubation, compared with an equivalent MAC value of isoflurane. We have confirmed the finding [6] that 1 MAC of desflurane resulted in a decrease in systolic arterial pressure and that in 44 % of patients this was clinically significant (table 2). We have also shown that a similar decrease in systolic pressure occurred with isoflurane. The difference in systolic arterial pressure during surgery between the two groups was not significant in our study. However, given the small numbers in the groups and the large variability around the mean value, the power of the test was only 0.4. In order to reject the null hypothesis (that there was no difference in systolic arterial pressure between the two groups) a total of 250 patients would be required, assuming that the size of the difference between the two treatment groups remained the same [9]. The increased number of apnoeas noted in the isoflurane group may reflect slower recovery. The prolonged apnoeic episodes (> 15 s) noted were distinct from breath-holding which we had predefined. Taylor

Decrease in SAP ⩾ 10 %	9	7
Decrease in SAP ⩾ 30 %	3	4
Breath-holding	4	2
Apnoea	3	0

and Lerman have suggested that because of the speed of recovery after desflurane anaesthesia, airway complications at extubation are unlikely [5], and we are not aware of any cases documented in the paediatric literature.

The anaesthetic technique chosen did not attempt to reflect routine clinical practice for general anaesthesia for pyloromyotomy. It was used as a means of comparing the effects of isoflurane and disflurane at equivalent MAC values for a standard period of time in neonates undergoing a short surgical procedure. The technique was a model to allow us to determine the differences in recovery characteristics of these two agents. The slightly lesser dose of thiopentone than that recommended by Hatch and Sumner [10] was chosen to minimize the ventilatory depressant effects of any residual i.v. agent at the end of the procedure. In order to ensure standardization of the anaesthetic, an end-tidal concentration of 1 MAC of agent was maintained until completion of the operation. Thus there was no tailoring of MAC levels as might occur in practice and no external stimulation allowed in order to facilitate awakening. Although not studied formally, it was our clinical impression that patients in the isoflurane group were sleepier and slower to recover than those in the desflurane group. Longer term data on respiration and sedation in the postoperative period would be advantageous.

In many respects, desflurane appears to be an impractical agent. It is expensive, requires a special vaporizer, and in paediatric practice has been associated with significant ventilatory complications on inhalation [5, 6]. However, it has the desirable characteristics of rapid emergence from anaesthesia because of its low blood:gas and tissue:gas solubilities. While these properties may be of little benefit in routine paediatric anaesthesia for healthy children undergoing short procedures, they may become increasingly relevant in the ex-premature infant. These patients are at increased risk from postoperative ventilatory complications such as apnoeic spells, with an incidence correlating inversely with gestational age and weight [11, 12]. Inhalation and i.v. anaesthetic agents exacerbate this problem by depressing immature ventilatory control mechanisms. Central nervous system depressant effects may be reduced further if desflurane is used at a lower concentration than 1 MAC. This could be achieved if inhalation anaesthesia was used to produce "insensibility" in combination with a regional technique or a local anaesthetic block.

If it is agreed that there are advantages in using desflurane in this particular group of patients, cost becomes an important consideration. Taking the example of a 3-kg infant using a fresh gas flow of 1300 ml min^{-1} [13], 1 h of desflurane used at 1 MAC for an infant is estimated to cost £5.47 per hour compared with £1.91 for 1 MAC of isoflurane. This moderate increase in anaesthesia cost becomes irrelevant if the use of desflurane enables postoperative extubation and thus avoids intensive care admission.

Perioperative changes in α_1-acid glycoprotein concentrations in infants undergoing major surgery

P. D. BOOKER, C. TAYLOR AND G. SABA

Summary

α_1-Acid glycoprotein (AAG) is an acute phase protein that is responsible for binding basic drugs such as bupivacaine. In order to determine how AAG concentrations change in response to surgical stress, arterial blood samples were obtained from 50 infants undergoing major surgery, at induction of anaesthesia and daily for the next 7 days. AAG concentrations were measured using a rate nephelometric technique. The overall mean preoperative AAG concentration was 0.38 (SD 0.16) mg ml^{-1}, although concentrations were significantly greater in infants undergoing urgent surgery compared with those undergoing elective surgery ($P = 0.02$). There were no significant correlations between gestational or postnatal age and preoperative AAG concentration. Mean AAG concentrations increased to 0.76 (0.18) mg ml^{-1} by day 4 after surgery and stayed at that concentration thereafter. Infants with preoperative AAG concentrations < 0.38 mg ml^{-1} showed a greater percentage increase in postoperative AAG concentrations than did infants with preoperative AAG concentrations > 0.38 mg ml^{-1} ($P = 0.001$). We conclude that preoperative measurement of AAG may identify those infants most at risk of drug toxicity in the early postoperative period. (*Br. J. Anaesth.* 1996; **76**: 365–368)

Key words
Anaesthesia, paediatric. Protein, α_1-acid glycoprotein. Infants.

Plasma protein binding of drugs may have significant pharmacodynamic implications, because it is the unbound moiety that diffuses most readily across biological membranes, reaches receptor sites to produce pharmacological effects and is available for elimination from the body. Although albumin (ALB) has a greater binding capacity than α_1-acid glycoprotein (AAG), AAG has much greater drug affinity for drugs with pK_a values of 8 or more, and binding of basic drugs decreases in AAG-deficient plasma [1, 2]. However, changes in protein binding are only important clinically for drugs which are highly bound to plasma proteins, such as bupivacaine (96% bound) [3], sufentanil and alfentanil (both 92% bound) [4]. If variations occur in the plasma concentrations of AAG, then the free plasma concentration of the bound drug can vary considerably, whereas the total concentration of the drug in plasma is only slightly affected.

The normal average plasma concentration of AAG in a healthy adult is 77 mg ml^{-1}, although there is great individual variation [5]. Many physiological factors influence AAG concentrations, including time of day [6], age [7, 8], sex [5, 7], pain [9] and nutritional status [10, 11]. Newborn infants may have very low plasma concentrations of AAG (and ALB) which tend to increase with age, to reach adult values by about 10 months of age [12]. Moreover, AAG is one of several plasma proteins synthesized by the liver; its concentration changes in response to various stressful stimuli, such as trauma [13], burns [14], malignancy [15] or infection [12, 16]. Thus the concentrations of "acute phase proteins" would be expected to change after major surgery, as has been shown in adults [17, 18], although this has not been confirmed in infants or children.

The latency period and extent of the change in AAG concentrations may be expected to have significant clinical implications for infants undergoing major surgery, as these patients are most likely to be receiving infusions of local anaesthetic or opioids in the immediate postoperative period. Therefore, in an attempt to define further the changes in plasma protein concentrations that may occur in this group of patients, we measured AAG plasma concentrations in infants requiring major surgery, both before and daily for 7 days after surgery.

Patients and methods

We obtained local Ethics Committee approval and written, informed consent from the parents of 116 infants, aged 3–200 postnatal days, presenting for major abdominal, thoracic or cardiac surgery and expected to require prolonged postoperative intensive care. Patients with tumours or suspected infection were excluded. The clinical notes were examined to determine maturity at birth and the gestational age of each infant at the time of surgery was calculated accordingly.

After induction of anaesthesia, a 0.5-ml arterial blood sample was obtained. This sampling was repeated every morning for the next 7 days or until

the arterial cannula was removed, whichever was sooner. We obtained all eight samples from 50 infants and blood was analysed for AAG using a rate nephelometric immunoassay technique (Beckman Array 360 System), which has a sensitivity of ±3%. All patients were given peroperative analgesia using opioids, local anaesthetic drugs, or both; infusions of opioids were continued into the postoperative period for as long as was deemed clinically appropriate.

Daily full blood counts, bacteriological cultures and measurement of C-reactive protein (CRP) were performed routinely. If there was any clinical suspicion of infection together with a $>50\%$ increase in leucocyte count or CRP, or $>50\%$ decrease in platelet count after the second post-operative day, or positive bacteriological cultures, or both, the AAG data for that patient were subsequently discarded. Routine biochemical monitoring of these patients included hepatic function tests every 2 days, or more frequently if indicated clinically. In addition to glucose infusions to maintain normal calorie intake, all patients were given protein supplementation either enterally (formula or breast milk) or i.v. (Primene 10%, Clintec) by day 3 after surgery, according to our normal clinical practice.

Two sample *t* tests were used to compare mean AAG concentrations between male and female infants, between infants with preoperative AAG concentrations < 0.38 mg ml^{-1} and infants with preoperative AAG concentrations $\geqslant 0.38$ mg ml^{-1}, and between infants requiring urgent and elective surgery. Kendall's tau-b rank correlation coefficient was used to assess associations between age and preoperative AAG concentrations.

Results

The mean preoperative plasma AAG concentration was 0.38 (SD 0.16) mg ml^{-1}, although there was wide inter-patient variation (range 0.07–0.78 mg ml^{-1}). Figure 1 shows the poor correlation between pre-operative AAG concentration and gestational age (correlation coefficient, $r = 0.09$; $P = 0.09$); a similar correlation existed for AAG concentration and postnatal age ($r = 0.07$; $P = 0.14$).

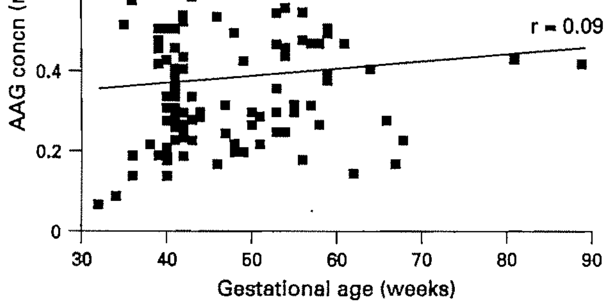

Figure 1 Individual plasma concentrations of α_1-acid glycoprotein (AAG) in 116 infants, obtained before operation, plotted against gestational age.

Table 1 Gestational age, postnatal age and preoperative plasma protein concentrations (mean (SD or range)) in males and females. AAG = α_1-acid glycoprotein

	Male ($n = 64$)	Female ($n = 52$)	*P*
Gestational age (weeks)	45.5 (34–71)	49.6 (32–89)	0.03
Postnatal age (weeks)	6.69 (0.0–31.4)	10.4 (0.0–51.0)	0.05
AAG concn (mg ml^{-1})	0.42 (0.17)	0.33 (0.14)	0.002

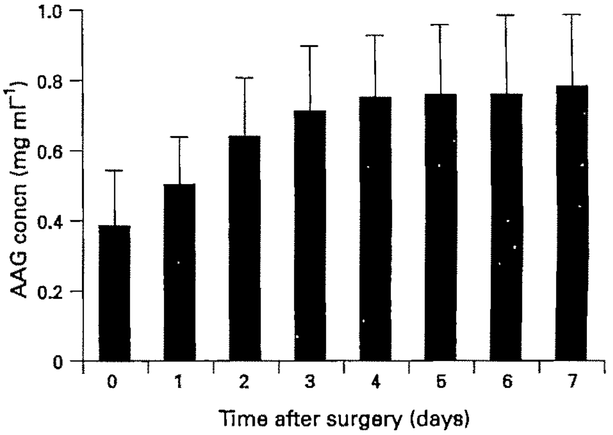

Figure 2 Mean (SD) plasma concentrations of α_1-acid glycoprotein before ($n = 116$) and after ($n = 50$) major surgery in young infants.

There was a significant difference between the sexes in mean AAG concentrations ($P = 0.002$) (table 1). Female infants had a mean gestational age of 49.6 (11.1) weeks compared with males who had a mean gestational age of 45.5 (8.0) weeks ($P = 0.03$). There were similar differences in postnatal age between the sexes ($P = 0.05$).

There was an increase in mean AAG concentration, to 0.76 (0.18) mg ml^{-1}, by day 4. Thereafter, AAG concentrations remained at or around this elevated concentration for the duration of the study (fig. 2).

Patients ($n = 29$) in whom preoperative values of AAG were less than the mean (0.38 mg ml^{-1}) were compared with those patients ($n = 21$) in whom preoperative AAG values were at or greater than the mean value (obtained from 116 infants). These data show that those infants with low preoperative AAG values had a much greater increase in postoperative values than did the group with higher preoperative AAG values ($P = 0.001$) (table 2).

Table 3 shows the mean perioperative AAG concentrations in infants requiring urgent compared with those requiring general surgery; there was a significant difference between the groups in pre-operative values, despite the gestational age in the elective surgery group being significantly older than in the urgent surgery group. AAG concentrations after surgery did not differ significantly between the

Table 2 Differences in mean AAG concentrations between postoperative values and preoperative concentration expressed as percentage change (SD). Patients ($n = 29$) in whom preoperative values were less than the mean (0.38 mg ml^{-1}) (group A) were compared with those patients ($n = 21$) in whom preoperative values were at or greater than the mean (group B)

Day after surgery	% Change in group A	% Change in group B	*P*
1	85.5 (50.3)	27.9 (19.1)	0.001

3	209.1 (109.5)	57.1 (35.9)	0.001
4	198.4 (94.2)	60.3 (32.7)	0.001
5	241.1 (114.3)	74.5 (57.7)	0.002
6	230.7 (123.7)	80.2 (69.5)	0.017
7	262.2 (121.2)	83.5 (62.9)	0.013

groups at any time. There were no significant differences in gestational age or perioperative AAG concentrations between infants requiring cardiac and those requiring abdominal surgery.

Discussion

The therapeutic safety margin for many analgesic drugs is reduced in infancy, because of increased sensitivity to the respiratory depressant effects of opioids [19], immature drug elimination pathways [19, 20] and, as we have now confirmed indirectly, a reduction in the plasma protein binding of drugs [21, 22]. Although the provision of postoperative analgesia in this age group is receiving increasing attention [23, 24], there are few data on plasma protein binding of analgesic drugs in infancy.

This study has confirmed previous neonatal studies [12, 16] showing that mean plasma concentrations of AAG in infants are about 50% of those in healthy adults. The large inter-patient variation seen in AAG concentrations reflects not only general individual variation but also the diversity in preoperative "stress". We compared preoperative AAG concentrations in infants who required elective surgery with those requiring urgent surgery, and found a significantly lower concentration in the elective surgical group ($P = 0.02$). Although these latter infants were significantly older ($P = 0.001$), a factor which should have increased the AAG concentration, they were less sick and presumably less "stressed" than those infants requiring urgent surgery. As would be expected, the type of surgery had no significant effect on preoperative AAG concentrations.

Previous studies have shown that AAG concentrations increase with increasing gestational age between 28 weeks and term [12, 16, 25], reaching adult concentrations by about 10–12 months of age [12, 26]. Our results agree with the previous findings of Bienvenu and colleagues [12] who found that, from the third postnatal day, the influence of gestational age on AAG concentrations was insignificant. Our finding of a significant difference in preoperative AAG concentrations between males and females is in contrast with previous neonatal [16] and adult [4] studies which showed little difference between the sexes, but supports a larger adult study [5]. This apparent anomaly may be explained by one neonatal study [25] which found no significant difference between the sexes at birth but a difference after the fourth day of life. Although our females were significantly older than the males, they had significantly lower mean preoperative AAG concentrations; this age difference in our male and female groups thus makes the AAG concentration difference between the sexes meaningful.

We have shown that most infants had an increase in AAG concentration in response to major surgical trauma, and by 4 days after surgery the AAG concentrations had doubled to 0.76 mg ml^{-1}, irrespective of the type or urgency of the surgery. Infants with preoperative AAG concentrations > 0.38 mg ml^{-1} showed a smaller percentage increase in the postoperative period than those infants with preoperative AAG concentrations < 0.38 mg ml^{-1}. We postulate that the higher preoperative values in the more stressed infants undergoing urgent surgery, reflects a sharp increase in hepatic AAG production that occurred before operation. The rate of increase in AAG production thereafter was consequently less than in those individuals who began to increase their hepatic AAG production only in response to surgical stress. However, the sickest neonates, particularly those with clinically and biochemically significant signs of hepatic dysfunction, exhibited little change and concentrations remained less than 0.5 mg ml^{-1}, often decreasing from their preoperative value. Low numbers of such patients and the lack of a widely accepted objective scoring system precluded separate

Table 3 Gestational age (mean (range)) and perioperative AAG concentrations (mean (SD) mg ml^{-1}) of infants requiring elective surgery compared with those requiring urgent surgery and in infants requiring abdominal surgery compared with those requiring cardiac surgery. AAG = α_1-acid glycoprotein

analyses of patients on the basis of severity of sickness in the postoperative period. However, one adult study has suggested that AAG concentrations decrease in proportion to the degree of hepatic dysfunction [27].

We suggest that preoperative measurement of AAG concentration should be performed in all infants undergoing elective major surgery who are expected to receive prolonged bupivacaine infusions in the postoperative period. Bupivacaine toxicity is not unknown in this age group [28] and this phenomenon may be related to low plasma protein concentrations. The maximum bupivacaine dose should be reduced in infants with preoperative AAG concentrations < 0.3 mg ml^{-1} and in infants with significant hepatic dysfunction.

Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone†

H. J. SPENS, G. B. DRUMMOND AND P. K. WRAITH

Summary

Changes in the expiratory dimensions of the rib cage and abdomen on induction of anaesthesia with eltanolone, propofol and thiopentone were measured in 76 patients using respiratory inductance bands. Calibration of the respiratory inductance plethysmograph was by simultaneous flow measurement with a pneumotachograph. Movement of the vertebral column was restrained with a rigid mattress to allow volume change to be estimated more accurately from rib cage and abdominal dimensions. Rib cage volumes decreased by a median of 125 ml, while the median change in the abdominal compartment was 0. These findings suggest that a reduction in rib cage volume may contribute to the decrease in functional residual capacity after induction of anaesthesia, but that changes in the diaphragmatic–abdominal compartment are not important. (*Br. J. Anaesth.* 1996; **76**: 369–373)

Key words

Lung, volume. Lung, functional residual capacity. Muscle respiratory. Anaesthetics i.v., propofol. Anaesthetics i.v., thiopentone. Anaesthetics i.v., eltanolone.

It is generally accepted that induction of anaesthesia in supine humans is associated with a reduction in functional residual capacity (FRC) of approximately 20% [1]. Changes in chest wall configuration are probably responsible, either by inward movement of the rib cage or by cephalad movement of the diaphragm [2].

Previous studies of changes in chest wall dimensions at induction of anaesthesia have reported inconsistent results. Rib cage dimensions decreased in some studies but not in others. Abdominal dimensional changes, used to infer movement of the diaphragm, have been even less conclusive [3–7].

Possible reasons for these discrepancies include small sample size and different measuring techniques used, but another potential source of error is spinal movement. Flexion or extension of the spine changes rib cage and abdominal dimensions without a change in lung volume [8]. Spinal movement occurs on induction of anaesthesia [2] and invalidates the assumption of two degrees of freedom implicit in the Konno and Mead analysis of chest wall movement [9]. A more recent study [10] measured dimensional changes in rib cage and abdomen while preventing spinal movement, and reported a reduction in chest wall dimensions on induction of anaesthesia, but no attempt was made to assess possible volume changes.

Therefore, we have measured the changes in the dimensions of the rib cage and abdomen on induction of anaesthesia in a large number of patients while firmly supporting the spine, and estimated the volume changes and contribution of the rib cage and diaphragmatic–abdominal compartments to the reduction in FRC that occurs on induction of anaesthesia. As a previous study using this method [11] reported different results for thiopentone compared with propofol, we have compared three i.v. induction agents.

Patients and methods

All patients were part of a larger study on the ventilatory effects of eltanolone compared with propofol and thiopentone. This study was approved by the local Ethics Committee, and informed consent was obtained from each patient.

We recruited 76 patients, aged 18–65 yr, of both sexes, ASA I or II, undergoing elective surgery. We excluded patients who were obese (more than 50% above ideal weight for height, Metropolitan Life Insurance Company scale), pregnant, had significant respiratory disease or anaesthetic drug allergy or who had abused alcohol or other substances. Patients received no premedication and were allocated randomly to receive eltanolone 0.75 mg kg^{-1}, propofol 2.5 mg kg^{-1} or thiopentone 4 mg kg^{-1} for induction of anaesthesia. These doses have been shown to be approximately equipotent [12, 13].

On arrival in the anaesthetic room, an i.v. cannula was inserted and patients were positioned on a "Vac-Pac" mattress (Howmedica). This is filled with polystyrene beads and thus conforms exactly to the curvature of the spine. Air was then evacuated from the mattress causing it to become rigid, preventing spinal movement.

Respiratory inductance bands were placed around the chest immediately below the axillae, and around the abdomen, at the level of the umbilicus. These

†Presented in part at the Anaesthetic Research Society, London Meeting, November 11–12, 1994 (*British Journal of Anaesthesia* 1995; 74: 472P).

were connected to a respiratory inductance plethysmograph (RIP), made by the Edinburgh University Department of Medical Physics. The signal output was AC-coupled with a time constant of approximately 2 min. The resulting signals, which represent changes in cross-sectional area of the rib cage and abdomen with respiration and which are accepted as proportional to compartment volume, were recorded on a lap-top computer using the commercial respiratory monitoring software Cardas (version 2.07 advanced, Oxcams, Oxford), running in MS-DOS (version 6.20).

Patients breathed 35% oxygen from a T-piece through a screen pneumotachograph (F100L, Mercury Electronics) and a tight fitting face mask with a wide pneumatic seal (Downs CPAP mask No. 9002, Vital Signs Inc., NJ, USA), held in place bimanually by the anaesthetist. The pneumotachograph was connected to a differential pressure transducer (0–10 mm H_2O, Furness) and the resulting flow signal was also recorded on the computer. The system was calibrated in the laboratory using a series RT200 calibration analyser (Timeter Instrument Corporation, Missouri, USA) and the voltage output was linear against an input flow of up to 40 litre min^{-1}. Immediately before each study, calibration was checked against a flowmeter (whose accuracy had also been verified in the laboratory), and was considered acceptable if the error was less than ±5%.

After a period of 3–5 min of stable breathing, the induction agent was administered over 30 s and RIP and flow signals were recorded for another 4 min. The jaw was supported gently by the anaesthetist to prevent upper airways obstruction. No other anaesthetic agent was administered during this time. The moment of loss of consciousness was noted from when the patient dropped a metal rod held between thumb and index finger. After completion of this study period, anaesthesia was continued as appropriate for clinical management.

The RIP signals (mV) were calibrated against the integrated flow signal (ml) by a multiple linear regression technique [14], using a stable 30-s period before induction of anaesthesia, and the volume–motion coefficients (ml mV^{-1}) for the rib cage and abdomen were calculated. The end-expiratory positions of the rib cage and abdomen were taken from a line fitted by eye on the RIP trace over approximately 1 min immediately before induction (baseline) and from the point of maximal change after loss of consciousness, and the difference (mV) was measured as shown in figure 1. These changes were then multiplied by their respective volume–motion coefficients to estimate the volume change of each compartment on induction of anaesthesia for each patient.

The consistency of the RIP calibration method was assessed as follows. Ten sets of patient data were selected randomly, and from each of these sets of data the 10 breaths immediately before the 30-s period actually used for calibration were analysed. The percentage difference between the RIP derived tidal volume (V_T) and the pneumotachograph derived V_T was then calculated for each of these breaths.

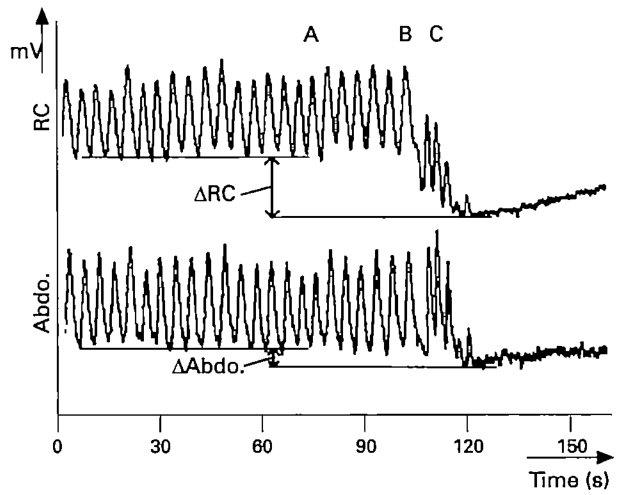

Figure 1 Typical respiratory inductance plethysmograph recording. A and B = start and end of administration of induction agent, respectively; C = moment of loss of consciousness. ΔRC and ΔAbdo. = measured changes in the end-expiratory position of the rib cage and abdomen after induction.

Data were analysed using the Minitab statistical package (release 8.2), in MS-DOS (version 6.20). Changes in chest wall volumes from baseline were tested using the Wilcoxon test and between-group changes were compared with the Kruskal–Wallis test. $P < 0.05$ was considered significant.

Results

Of the original 76 patients studied, results were available for analysis from 59. Reasons for the missing data are shown in table 1. The characteristics of those included are summarized in table 2. There were more males in the propofol group and more females in the thiopentone group than in the eltanolone group, with a corresponding bias in weight and height.

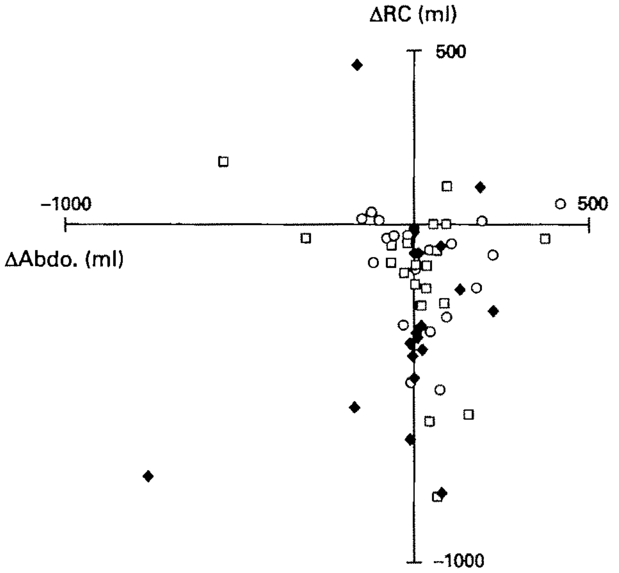

Figure 2 Change in rib cage volume (ΔRC) *vs* change in abdominal volume (ΔAbdo.) for each patient in the eltanolone (○), propofol (◆) and thiopentone (□) groups.

The consistency of the RIP calibration showed that the mean overall RIP derived V_T was 3.8 % less than the mean pneumotachograph derived V_T. Sixty-two percent of values of RIP V_T lay within ±10 % of pneumotachograph V_T, and 92 % were within ±20 %.

Table 3 shows the median changes in the volume of the rib cage and abdominal compartments, and the total volume change of the chest wall measured from the individual totals of rib cage and abdominal volume changes. In general, the changes in compartment volume began approximately 30 s after the start of administration of the induction agent and developed over approximately 30 s. Loss of consciousness occurred at a mean of 45 s after the start of injection. The decrease in rib cage volume in patients receiving propofol was greater than in the two other groups, but a Kruskal–Wallis test indicated that the groups were not significantly different ($P = 0.1$). Other differences between groups were even less marked. Because there were no significant differences between the three groups, the changes in compartmental volumes were pooled and analysed together.

Rib cage volumes increased in nine subjects and decreased in 50, with a median overall reduction of 125 ml. Abdominal volumes increased in 29, decreased in 22, and did not change in eight (median change = 0). The median overall reduction in chest wall volume, measured from the total change in rib cage volume and abdominal volume, was 136 ml. The changes in rib cage volume and chest wall volume were significantly different from 0 ($P < 0.05$), but the change in abdominal volume was not (median change 0, interquartile range −35 to 71 ml). The commonest pattern of change was a reduction in rib cage volume and a smaller increase in abdominal volume (fig. 2).

Discussion

These results confirm that induction of anaesthesia with i.v. agents is associated with a decrease in chest wall volume. However, the magnitude of this change was small, with a median reduction of only 136 ml. A reduction in the volume enclosed by the rib cage was almost entirely responsible for the overall volume change, with a median change in abdominal volume of 0. Our results were absolute values but previous studies have often expressed data as a percentage of FRC. We did not measure FRC and did not attempt to relate the changes we found to a predicted lung volume.

A potential source of error in any study of this type is calibration of RIP. In this study a multiple linear regression technique (MLR) was used which depends on a natural breath-to-breath variation in the contribution of rib cage and abdominal motion to respired volume. Unlike the isovolume method [9] MLR does not require patient co-operation to learn a difficult respiratory manoeuvre, or a change in posture, as used in other methods [15], which may in itself alter the volume–motion coefficients of rib cage and abdomen [16, 17]. However, the statistical association of rib cage and abdominal movement can make the predictive value of one component of the MLR less relevant.

The validation results in the present study showed that the precision and accuracy of our calibration technique were comparable with those reported by other workers, using a variety of calibration methods, when posture is not changed [18–20]. Possible problems with our method include the fact that we used a single calibration period rather than averaging the volume–motion coefficients from several, and that we used the whole respiratory cycle for the MLR analysis rather than only the more stable middle portion of inspiration. However, for the purposes of the present research, we feel our method is adequate.

There may also have been other sources of error such as unrecognized mask leaks. To minimize this we used a face mask with a wide pneumatic rim, applied water-soluble jelly if facial stubble was present, and held the mask in place with two hands allowing manual detection of escaping gas. Use of a carbon dioxide monitor in some patients showed a normal waveform with normal end-tidal values, confirming our belief that significant gas leaks did not occur.

The median reduction in chest wall volume of 136 ml after i.v. induction of anaesthesia in this study was remarkably small. Other workers, using helium dilution, nitrogen washout and body plethysmography techniques to measure FRC have reported larger reductions, from 300 to 700 ml [3, 21–24]. Many factors may explain these differences; first, as we were using an AC-coupled system, the relationship between the time constant of our RIP (2 min) and the time course of the change in end-expiratory compartment volume (30 s) may have resulted in a small underestimate of the volume changes. A longer time constant would reduce this error, but would increase the time needed to reach a steady baseline. Second, it has been postulated that increases in the volume of blood and tissue in the thoracic cavity may occur on induction of anaesthesia. This may decrease the volume of intrathoracic gas and hence FRC without affecting rib cage and abdominal dimensions. However, in awake subjects, splints around the lower limbs decrease the volume of intrathoracic gas but increase chest wall dimensions [25], and recent work using CT scanning showed a reduction in chest wall volume on induction of anaesthesia but no change in intrathoracic blood or tissue volume [2].

Alternatively, the third degree of freedom of movement of the chest wall [8] may be responsible for the difference in magnitude of FRC reduction between our results and those of other workers. Unlike other investigators we intended to eliminate this freedom of movement by firmly supporting the spine. It has been shown [2] that induction of anaesthesia can result in an increase in the curvature of the thoracic spine. The Vac-Pac mattress may eliminate skeletal movement in these circumstances [26]. Therefore, in other studies of FRC a change in thoracic flexion could cause an additional decrease in intrathoracic gas, which did not occur in our patients. Other possible causes of this discrepancy relate to the timing of FRC measurements. In studies using helium dilution, nitrogen clearance or body plethysmography to measure FRC, some time elapsed between induction of anaesthesia and FRC measurement. Over 15 min, FRC may be reduced in conscious subjects by breathing oxygen-enriched gas mixtures [27] and this effect could contribute to the greater decreases found in previous studies. A delay in measurement of FRC may also allow onset of phasic expiratory activity in the abdominal muscles [2] which could also reduce FRC. This may not have been seen in this study as measurements were made immediately after induction, often during a period of apnoea. This postulate is supported by studies measuring changes in end-expiratory lung volume with spirometry immediately after induction [28, 29], where smaller reductions in FRC of only 243 and 188 ml were found, closer to our results.

A final possible explanation for these differences might be that our study, and others reporting FRC changes of a similar magnitude [28, 29], used face-mask anaesthesia, while those workers who found larger reductions in FRC used tracheal tubes to maintain the airway. This may affect FRC. Bickler, Dueck and Prutow [30] found only a 3.5 % reduction in FRC in patients breathing via a face mask, compared with a 22 % reduction in patients breathing via a tracheal tube. The mechanism of this effect is not yet clear. Thus it can be seen that there are several possible reasons why we found smaller reductions in chest wall volume after induction of anaesthesia than would be expected from the results of other studies measuring FRC.

We found a reduction in rib cage dimensions on induction of anaesthesia, consistent with other studies [2–4, 6, 10], although earlier work failed to demonstrate this [5, 7]. The likely cause is a reduction in tonic activity in the inspiratory muscles of the rib cage. The presence of tonic activity in the scalenes, sternocleidomastoid and, to a lesser extent, in the intercostals has been demonstrated [31]; induction of anaesthesia with thiopentone abolished this. However, a study using implanted electrodes failed to demonstrate tonic activity in the parasternal intercostals [2], but the parasternal intercostals may not be representative of rib cage postural muscles [32].

We found no overall change in abdominal volumes on induction of anaesthesia, indicating that displacement of the diaphragm does not make an important contribution to the reduction in FRC. However, measurements of abdominal dimensions do not necessarily reflect changes in diaphragmatic position or length [33]. Other workers [2, 3, 34, 35] who have made direct estimates of diaphragm movements on induction of anaesthesia using x-ray and ultrasound imaging have also reported inconsistent results, and concluded that changes in length or position of the diaphragm do not contribute significantly to the reduction in FRC on induction of anaesthesia.

We found no significant differences between the eltanolone, propofol and thiopentone groups. This is at a variance with the observations of Grounds and co-workers [11] who, using similar methods, found a reduction in chest wall volume using propofol for induction of anaesthesia, but found an unexplained increase with thiopentone. However, our findings agree with those of a study reporting changes in end-expiratory lung volume after induction [28], where no significant difference was found between the effects of propofol and thiopentone. It is also interesting to note that inhalation induction of anaesthesia with halothane was associated with a reduction in FRC of a broadly similar magnitude [2] to that which we found with i.v. agents.

In summary we have found that induction of anaesthesia with three different i.v. agents produced a small decrease in chest wall volume. This was caused mostly by a reduction in rib cage volume; the changes in diaphragmatic length or position were unimportant. The time course of this decrease suggests a loss of tonic inspiratory activity, and this decrease in rib cage volume contributes to the reduction in FRC seen on induction of anaesthesia.

Slow ventilatory dynamics after isocapnic hypoxia and voluntary hyperventilation in humans: effects of isoflurane

A. DAHAN, J. VAN KLEEF, M. VAN DEN ELSEN, R. VALK AND A. BERKENBOSCH

Summary

Short-term potentiation (STP) of breathing refers to respiratory activity that persists at termination of a primary stimulus and is not related just to the dynamics of chemoreceptors. In humans, STP is activated by brief episodes of hypoxia and voluntary hyperventilation (VHV). STP exerts a stabilizing influence on breathing pattern. To investigate the effects of a subanaesthetic concentration of isoflurane on STP, we studied recovery from mild and moderate hypoxic hyperpnoea and VHV. Experiments were performed in eight healthy volunteers. If necessary, subjects were aroused to maintain a state of wakefulness. In the hypoxic studies, a control study involved 1 min of isocapnic hypoxia (end-tidal $P\text{O}_2$ ($P\text{E}'_{\text{O}_2}$ 6.1) kPa) followed by sudden transition to normoxia. In the isoflurane studies, 1 min of mild hypoxia (Iso-1 study: $P\text{E}'_{\text{O}_2}$ 6.2 kPa) and 1 min of moderate hypoxia (Iso-2 study: $P\text{E}'_{\text{O}_2}$ 5.7 kPa) were followed by sudden transition to normoxia during inhalation of 0.1 minimum alveolar concentration (MAC) of isoflurane. $P\text{E}'_{\text{CO}_2}$ was maintained at 5.9 kPa. In the VHV study, ventilatory recovery from 1 min of normoxic VHV was monitored before and during inhalation of 0.1 MAC of isoflurane. Subjects performed multiple transitions in each study. In the hypoxic studies, peak ventilation after 1 min of hypoxic stimulation did not differ between treatments. The averaged responses reached normoxic baseline after 56.3 (SEM 10.7) s in the control study ($n = 47$ transitions), 18.0 (3.3) s in the Iso-1 study ($n = 41$; $P < 0.05$ *vs* control) and 15.3 (2.4) s in the Iso-2 study ($n = 23$; $P < 0.05$ *vs* control). In the VHV studies, $\dot{V}\text{E}$ at termination of VHV was not different from baseline after 36 s in the control study. An immediate reduction to less than baseline ventilation, lasting 24 s, was present in the isoflurane study. We believe that shortening of the time required to reach baseline in the hypoxic studies, and hypoventilation at cessation of VHV in the isoflurane studies, are related to the inability to activate STP of breathing via an effect of isoflurane on respiratory neurones in the brain stem. Increasing the stimulus intensity during isoflurane inhalation (Iso-2 study) did not (re)-activate STP. (*Br. J. Anaesth.* 1996; **76**: 374–381)

Key words

Anaesthetics volatile, isoflurane. Ventilation, hypoxic response. Ventilation, hyperventilation. Hypoxia.

At termination of a respiratory stimulus, ventilatory activity (minute ventilation or phrenic nerve activity) that persists for seconds to minutes, not related only to the dynamics of peripheral or central chemoreceptors, is termed short-term potentiation (STP) of breathing (synonyms include ventilatory afterdischarge, central neuronal dynamics or respiratory memory) [1–3]. Among the various manoeuvres that make STP apparent are: termination of electrical stimulation of the carotid sinus nerve [4–6]; sudden cessation of brief episodes of hypoxia [3, 7–9]; and termination of voluntary hyperventilation (VHV) [10–14]. These manoeuvres yield a two-component change in minute ventilation ($\dot{V}\text{E}$) or phrenic nerve activity: an initial rapid decrease followed by a slower one. This slow decrease or decay is considered the manifestation of the STP of breathing. Studies in awake humans in which isocapnic hypoxia or isocapnic voluntary hyperventilation is induced to activate STP, demonstrated a time constant of the slow ventilatory decay of about 30 s [8, 10, 13] (and of about 4 s for the initial decrease in $\dot{V}\text{E}$) [8, 15]. STP is thought to originate within the pontomedullary brain stem involving neural networks that cause reverberating activity on stimulation [1].

A slow decay in $\dot{V}\text{E}$ or phrenic nerve activity at termination of hypoxia, VHV or carotid sinus stimulation may not always be present or its magnitude may be too small to be detected. This is because of mechanisms that override or counterinfluence the manifestation of STP or the inability to activate STP. Examples of the former are hypocapnia and sustained hypoxia (> 3 min). Both cause the absence or reduction of the amplitude of the slow ventilatory decay of STP but not its inactivation [4, 8, 16]. Previously, we have tested the effects of low concentrations of halothane on STP activation in humans [15]. The sudden termination of brief episodes of hypoxia caused the return of $\dot{V}\text{E}$ to baseline in 60 s in the control study and in 12 s in the halothane study. We related this finding to inactivation of STP of breathing through a direct effect of halothane on the pontomedullary brain stem. However, suggestions have been made that the ability to activate STP is related to stimulus intensity [3]. The ventilatory increase in the halothane study

Correspondence to A.D.

was less than 50% of control and may have been too small to exceed the threshold for activation of STP.

In the present study we have determined the pattern of breathing after 60 s of isocapnic hypoxic hyperpnoea and VHV in healthy volunteers before and during inhalation of low-dose isoflurane. Our main aims were: to investigate the influence of isoflurane on STP activation; to compare the influences of isoflurane on STP activation via stimulation of the peripheral chemoreflex pathway (hypoxic studies) and a suprapontine pathway (VHV studies); and to examine the effect of stimulus intensity on STP activation during inhalation of isoflurane. To do this, we determined ventilatory recovery from mild (end-tidal oxygen partial pressure ($P\mathrm{E}'_{\mathrm{O}_2}$ 6.2 kPa) and moderate hypoxic ($P\mathrm{E}'_{\mathrm{O}_2}$ 5.7 kPa) hyperpnoea. In order to prevent a reduction in the ventilatory response to hypoxia by isoflurane, we actively aroused the subjects during the studies. This procedure counter-influences the depressant effect of subanaesthetic isoflurane on the ventilatory response to acute isocapnic hypoxia [17].

Subjects and methods

We studied 10 healthy subjects (four females), aged 27–37 yr. The study was approved by the Leiden University Committee on Medical Ethics and informed consent was obtained. Subjects were asked to refrain from stimulants and depressants for at least 12 h before the experimental sessions. Before the study, on a separate day, all subjects performed a test study to determine the magnitude of their hypoxic responses. In that study four to five stepwise isocapnic decreases in $P\mathrm{E}'_{\mathrm{O}_2}$ from 14.5 to 6.2 kPa were applied. Hypoxia was maintained for 3 min. Subjects were excluded from further participation when their mean hypoxic response was 0.2 litre $\mathrm{min}^{-1}\,\%^{-1}$ or less.

During the study subjects were in a semi-recumbent position. An oronasal mask (Vital Signs, USA) was fitted before the study started. Airway gas flow was measured with a pneumotachograph connected to a differential pressure transducer (Hewlett-Packard, model 270, USA) and integrated electronically to yield a volume signal. This signal was calibrated with a motor-driven piston pump (stroke volume 1000 ml, at a frequency of 20 strokes min^{-1}). Corrections were made for the changes in gas viscosity as a result of changes in oxygen concentration of the inhaled gas mixture. The pneumotachograph was connected to a T-piece. One arm of the T-piece received a gas mixture with a flow of 50 litre min^{-1} from a gas mixing system, consisting of four mass flow controllers (Bronkhorst High Tec, F201–F203, The Netherlands) with which the flow of oxygen, carbon dioxide, nitrogen and isoflurane in nitrogen could be set individually at a desired level. Part of the nitrogen (5 litre min^{-1}) passed through an isoflurane vaporizer (Vapor 19.3, Dräger, Germany). During the control studies the vaporizer was kept in the "off" position. Flows were calibrated with flow resistance standards (Godart, The Netherlands). The instrumental deadspace was 250 ml. A Digital Equipment Corporation Programmable Digital Processor 11/23 microcomputer (IO, USA) provided control signals to the mass flow controllers, so that the composition of the inspiratory gas mixture could be adjusted to force the end-tidal carbon dioxide partial pressure ($P\mathrm{E}'_{\mathrm{CO}_2}$) and $P\mathrm{E}'_{\mathrm{O}_2}$ to follow a specific pattern in time.

The oxygen and carbon dioxide concentrations of the inspired and expired gases were measured with a gas monitor (Datex Multicap, Finland) by paramagnetic and infra-red analysis, respectively. The gas monitor was calibrated with gas mixtures of known concentrations. The isoflurane concentration was measured at the mouth with a Datex Ultima monitor (Finland). This monitor was calibrated with a gas mixture of isoflurane in nitrogen of known concentration. A pulse oximeter (Datex Satellite Plus, Finland) continuously monitored arterial oxygen saturation via a finger probe, $\dot{V}\mathrm{E}$, tidal volume ($V\mathrm{T}$), respiratory frequency (f), inspiratory time ($T\mathrm{I}$), expiratory time ($T\mathrm{E}$), $P\mathrm{E}'_{\mathrm{CO}_2}$, $P\mathrm{E}'_{\mathrm{O}_2}$ and arterial oxygen haemoglobin saturation from pulse oximetry were calculated and stored on a breath-to-breath basis.

HYPOXIC STUDIES

We used a computer controlled "dynamic end-tidal forcing system" to force the end-tidal gas concentrations to follow a prescribed pattern in time, independent of the ventilatory response [18]. The study was performed at a mild hypercapnic level with a $P\mathrm{E}'_{\mathrm{CO}_2}$ value of approximately 0.2–0.3 kPa above individual resting values. The reasons for this increase were two-fold: to perform control and isoflurane studies at similar $P\mathrm{E}'_{\mathrm{CO}_2}$ levels and to allow the end-tidal forcing system to adequately control $P\mathrm{E}'_{\mathrm{CO}_2}$ by manipulation of inspired carbon dioxide concentrations.

Initially, hypoxia was induced without isoflurane inhalation (control study). $P\mathrm{E}'_{\mathrm{O}_2}$ was lowered within three to four breaths from 14.5 to 6.1 kPa and maintained at this hypoxic level for 60 s. Thereafter $P\mathrm{E}'_{\mathrm{O}_2}$ was increased rapidly to baseline levels and maintained constant for a subsequent 120 s. Each subject performed 5–6 transitions out of hypoxia. During isoflurane inhalation each subject performed 4–6 transitions out of hypoxia ($P\mathrm{E}'_{\mathrm{O}_2}$ 6.2 kPa, Iso-1 study) and 2–3 transitions out of a deeper level of hypoxia ($P\mathrm{E}'_{\mathrm{O}_2}$ 5.7 kPa, Iso-2 study). Between transitions there was a 10-min interlude.

VOLUNTARY HYPERVENTILATION

Subjects were asked to voluntarily hyperventilate and were coached to increase their ventilation to about 60 litre min^{-1}. Respiratory frequency and tidal volume were set by the subjects. VHV was ended after 60 s at the command of one of the investigators. Subsequently, $\dot{V}\mathrm{E}$ was followed for 120 s after termination of VHV. Each subject was studied at least twice, with and without isoflurane inhalation. $P\mathrm{E}'_{\mathrm{CO}_2}$ was targeted at baseline level.

The hypoxic and VHV studies were performed on one morning session. Control studies always preceded the isoflurane studies.

The end-tidal isoflurane fraction was adjusted within 5 min to 0.125% (0.1 minimum alveolar concentrations (MAC) in the age group 25–40 yr [19]). This was done using an "overpressure" technique. Thereafter, a 20-min period preceded the isoflurane studies. The 20-min period represented 5 time constants for isoflurane brain uptake and equilibrium [20]. Throughout the studies, the end-tidal fraction was kept constant at the target level (0.125%) by manipulation of the vaporizer.

During the control and isoflurane (hypoxic and VHV) studies, the subjects listened to music. They were watched continuously by one of the investigators and instructed to keep their eyes open. If they closed their eyes we called the name of the subject and encouraged them to keep their eyes open. Data were discarded when the subject was unable to keep the eyes open.

DATA ANALYSIS: HYPOXIC STUDIES

For each transition, baseline $\dot{V}\text{E}$ was assessed by averaging over a 1-min time period before induction of hypoxia. Peak $\dot{V}\text{E}$ was determined by averaging the last two hypoxic $\dot{V}\text{E}$ breaths. The difference between peak $\dot{V}\text{E}$ and baseline $\dot{V}\text{E}$ was defined $\Delta\dot{V}\text{E}$. A two-way analysis of variance was performed on baseline $\dot{V}\text{E}$, peak $\dot{V}\text{E}$ and $\Delta\dot{V}\text{E}$. Differences between the three treatments (control, Iso-1 and Iso-2) were tested with the Student–Newman–Keuls test. Probability levels less than 0.05 were taken as significant.

To obtain information on the period of time that ventilation remained greater than baseline $\dot{V}\text{E}$, when normoxia followed hypoxia, we performed an ensemble average on the $\dot{V}\text{E}$ data of the transitions of individual subjects and on all acquired transitions. One ensemble average was performed for each of the three studies (control, Iso-1, Iso-2). The averages were calculated with linear interpolation at 3.0-s time intervals between breaths of the individual trials. By indexing on the time of the last hypoxic breath (i.e. $t = 0$), the first "non-hypoxic" data point was set at time $t = 3.0$ s. We plotted the ensemble average $\dot{V}\text{E}$ data points (± 2 SEM), which constitutes an approximately 95% confidence interval. We defined ventilation to be non-significantly different from baseline $\dot{V}\text{E}$ when the magnitude of baseline $\dot{V}\text{E}$ was within the range of the ensemble average $\dot{V}\text{E} - 2$ SEM of the first two consecutive breaths. The time at which this occurred was set at the first non-significantly different data point and defined as ΔT. An undershoot was defined as ensemble average $\dot{V}\text{E}$ data $+ 2$ SEM less than baseline $\dot{V}\text{E}$. When an undershoot occurred, the time of the first mean $\dot{V}\text{E}$ data point $- 2$ SEM which included the value of baseline $\dot{V}\text{E}$ was defined ΔT (see also fig. 1 of reference [8]). Analysis of variance was performed on ΔT obtained from the ensemble averages of individual subjects. Similar procedures were performed for $V\text{T}$, $T\text{I}$ and $T\text{E}$.

DATA ANALYSIS: VOLUNTARY HYPERVENTILATION

$\dot{V}\text{E}$ during VHV was determined by averaging the last 4 breaths of hyperventilation just before the command to end VHV. An ensemble average of all control and isoflurane transitions was performed similar to those of the hypoxic studies (see above). The data were indexed on the time of the last breath of VHV (i.e. the last breath before the command to terminate VHV).

All values are mean (SEM) unless otherwise stated.

Results

TEST STUDY

Two subjects had ventilatory responses smaller than 0.2 litre $\text{min}^{-1}\,\%^{-1}$. They were excluded from further participation. The ventilatory response of the remainder (three females, five males) ranged from 0.35 to 1.0 litre $\text{min}^{-1}\,\%^{-1}$.

HYPOXIC STUDIES

A total of 111 transitions were performed in eight subjects: 47 in the control study, 41 in the Iso-1 study and 23 in the Iso-2 study. Control of $P\text{E}'_{\text{O}_2}$ and $P\text{E}'_{\text{CO}_2}$ is shown in tables 1 and 2. The expiratory fractions of isoflurane were 0.126 (0.003)% and 0.127 (0.005)% in the Iso-1 and Iso-2 studies, respectively. All subjects were able to maintain their eyes open throughout the control and isoflurane studies.

During 1 min of hypoxic stimulation, $\dot{V}\text{E}$ increased from 15.7 (1.0) litre min^{-1} (baseline) to 25.1 (2.4) litre min^{-1} (peak hypoxia) in the control study

Table 1 Control of end-tidal $P\text{O}_2$ ($P\text{E}'_{\text{O}_2}$) for the first 30 s after transition out of hypoxia for the hypoxic studies. Control, $n = 47$; Iso-1, $n = 41$, 0.1 MAC of isoflurane; Iso-2, $n = 23$, 0.1 MAC of isoflurane. Hypoxia or time 0 is the last data point before the increase in inspired oxygen. Each data point is the ensemble average of all obtained runs. Values are mean (SEM). $^*P < 0.05$ *vs* baseline

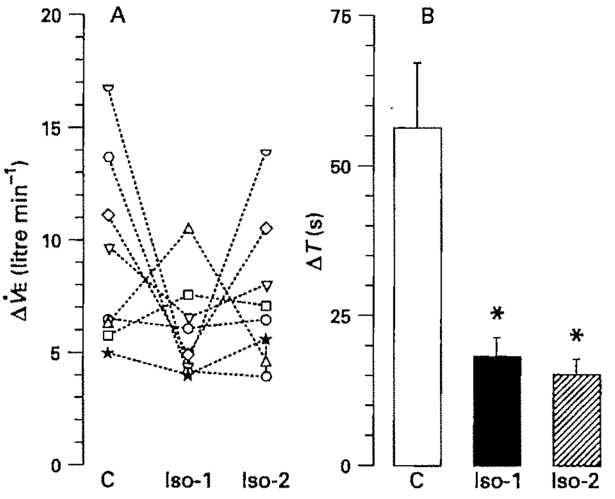

Figure 1 A: Mean ventilatory responses to 1 min of isocapnic hypoxia of individual subjects. B: Time required for $\dot{V}_E$ to return to baseline at termination of isocapnic hypoxia (ΔT). C = control study, $P_{E'_{O_2}}$ 6.1 kPa; Iso-1 = hypoxic response during inhalation of 0.1 MAC of isoflurane, $P_{E'_{O_2}}$ 6.2 kPa; Iso-2 = hypoxic response during inhalation of 0.1 MAC of isoflurane, $P_{E'_{O_2}}$ 5.7 kPa. Values are mean, SEM $^*P < 0.01$ *vs* control.

($\Delta\dot{V}_E$ 9.3 (1.5) litre min^{-1}), from 15.4 (0.6) to 21.5 (0.8) litre min^{-1} in the Iso-1 study ($\Delta\dot{V}_E$ 6.0 (0.8) litre min^{-1}) and from 15.5 (0.8) to 22.9 (1.8) litre min^{-1} in the Iso-2 study ($\Delta\dot{V}_E$ 7.5 (1.2) litre min^{-1}). The values of $\Delta\dot{V}_E$ for individual subjects is shown in figure 1A. Baseline $\dot{V}_E$, $\dot{V}_E$ at peak hypoxia and $\Delta\dot{V}_E$ did not differ significantly between the three studies.

After termination of hypoxia, the time required for $\dot{V}_E$ to reach baseline (ΔT) was 56.3 (10.7) s in the control study, 18.0 (3.3) s in the Iso-1 study ($P < 0.05$ *vs* control) and 15.3 (2.4) s in the Iso-2 study ($P < 0.05$ *vs* control) (fig. 1B). The ensemble averages of recovery from hypoxia of all obtained transitions are shown in figure 2 for the three studies. It is clear that an undershoot occurred in the Iso-1 (from $t = 21$ to 45 s) and Iso-2 (from $t = 18$ to 45 s) studies (see fig. 1).

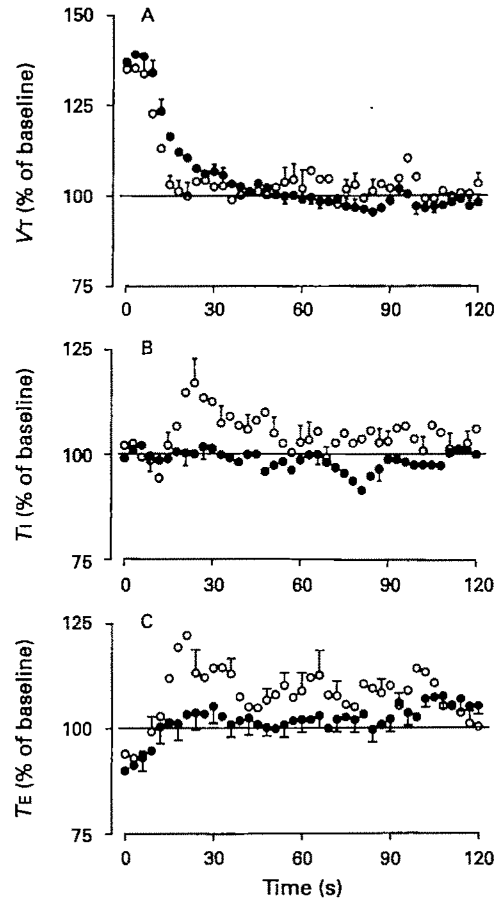

Figure 3 Ensemble averages of tidal volume (V_T) (A), inspiratory time (T_I) (B) and expiratory time (T_E) (C) of all transitions from hypoxia to normoxia (● = control; ○ = Iso-1). (See legend of fig. 2 for averaging procedure followed.)

In figure 3 we plotted the ensemble averages of the ventilatory components V_T, T_I and T_E of the control (closed circles) and Iso-1 (open circles) studies as a percentage of baseline values. In both studies the ventilatory increase at 1 min of hypoxia was caused by an increase in V_T and shortening of T_E. In the control study at cessation of hypoxia, V_T decreased

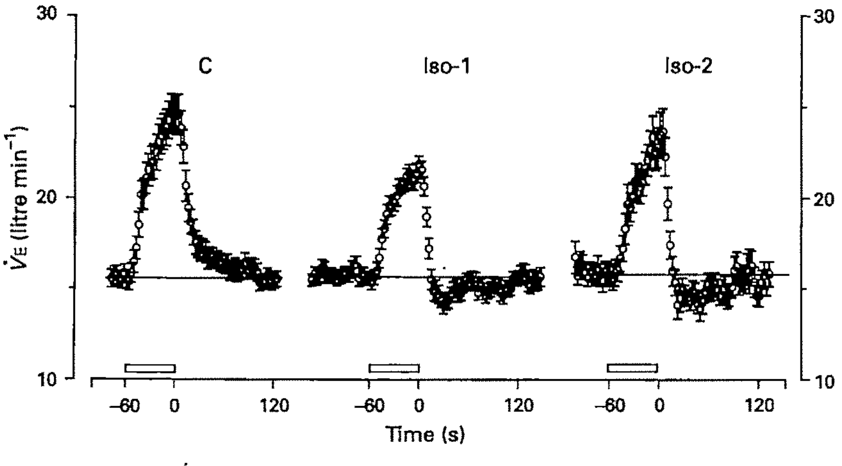

Figure 2 Ensemble averages of $\dot{V}_E$ data of all acquired transitions into and out of 1 min of isocapnic hypoxia. The averages (±2 SEM) were performed with linear interpolation at 3.0-s intervals between breaths of individual trials. Time $t = 0$ is the time of the last hypoxic breath. The first "non-hypoxic breath" is at $t = 3.0$ s. Horizontal line = baseline ventilation; bar = 1-min hypoxic period. C = Control study, $P_{E'_{O_2}}$ 6.1 kPa, $n = 47$; Iso-1 = hypoxic response during inhalation of isoflurane, $P_{E'_{O_2}}$ 6.2 kPa, $n = 41$; Iso-2 = hypoxic response during inhalation of isoflurane, $P_{E'_{O_2}}$ 5.7 kPa, $n = 23$.

Table 3 Control of end-tidal $P\mathrm{CO}_2$ ($P\mathrm{E}'_{\mathrm{CO}_2}$) for the voluntary hyperventilation (VHV) studies. VHV occurred from $t = -60$ s to $t = 0$ s. Baseline values were obtained from t -90 s to $t = -60$ s. Recovery: $t > 0$ s. Values are means (SEM). $^*P < 0.05$ *vs* baseline

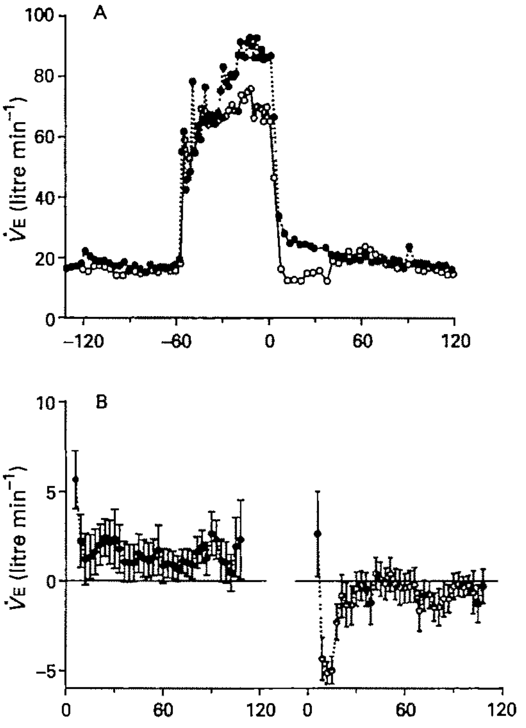

Figure 4 A: Effect of 0.1 MAC of isoflurane on ventilatory recovery from 1 min of voluntary hyperventilation. One control (●) and one isoflurane (○) experiment from a single subject are plotted. The slow decaying afterdischarge is seen in the control but not in the isoflurane experiment. Each dot is one breath. B: Ensemble averages of ventilatory recovery from voluntary hyperventilation (see legend of fig. 2 for the procedure followed). $\dot{V}\mathrm{E} = 0$ litre min^{-1} is baseline ventilation. First data point shown at $t = 6$ s. Data points are mean ± 2 SEM for the control ($n = 15$) (●) and isoflurane ($n = 15$) (○) studies.

slowly to baseline levels during the initial 51 s of normoxia. A small increase in $T\mathrm{E}$ from 90% to 100% of baseline occurred from $t = 0$ to 12 s of normoxia. The faster decay in $\dot{V}\mathrm{E}$ after hypoxia in the Iso-1 study and the undershoot below baseline was caused by changes in $V\mathrm{T}$, $T\mathrm{E}$ and $T\mathrm{I}$. Tidal volume reached baseline at $t = 18$ s, $T\mathrm{E}$ increased to ~ 125% of baseline at $t = 21$ s, and $T\mathrm{I}$ peaked to ~ 120% of baseline at $t = 27$ s of normoxia. The increases in $T\mathrm{E}$ and $T\mathrm{I}$ were followed by a slow decline towards baseline. The increase in $T\mathrm{I}$ was not immediate on cessation of hypoxia but started at $t = 15$ s of normoxia. The patterns observed in the Iso-2 study were similar to those observed in the Iso-1 study.

VOLUNTARY HYPERVENTILATION

All subjects were able to maintain their eyes open during both control and isoflurane studies. One subject failed to hyperventilate > 30 litre min^{-1} during inhalation of isoflurane. Her data were discarded from further analysis. Fifteen VHV studies during air breathing and 15 during inhalation of 0.1 MAC of isoflurane were obtained in seven subjects. Ventilation during VHV was similar in the control and isoflurane studies (control 66 (3.2) litre min^{-1} *vs* isoflurane 64 (2.5) litre min^{-1}). In contrast with the hypoxic studies, control of $P\mathrm{E}'_{\mathrm{CO}_2}$ was poor (table 3). In both studies, during VHV, $P\mathrm{E}'_{\mathrm{CO}_2}$ was consistently less than baseline values and during recovery from VHV consistently above baseline.

In figure 4A we have plotted a control and an isoflurane VHV study of one subject. In the control study, $\dot{V}\mathrm{E}$ showed an initial fast decrease followed by a slow decay. Recovery from VHV during inhalation of isoflurane displayed a fast decrease to baseline. The ensemble average of recovery from VHV is plotted in figure 4B. $\dot{V}\mathrm{E}$ remained greater than baseline for 36 s in the control study. At $t > 45$ s, $\dot{V}\mathrm{E}$ was greater than baseline for various periods. In the isoflurane study, $\dot{V}\mathrm{E}$ showed an immediate decrease to 5 litre min^{-1} below baseline followed by a slow increase (duration of undershoot 24 s).

Discussion

There was a tendency for the hypoxic ventilatory response of the Iso-1 study to decrease compared with control but this was not significant. In a previous study we observed that isoflurane at a MAC of 0.1 reduced the ventilatory response to 4 min of isocapnic hypoxia ($P\mathrm{E}'_{\mathrm{O}_2}$ 5.9 kPa) by about 50% in a similar group of subjects [21]. In retrospect, we determined the ventilatory response to 1 min of hypoxia, in a similar manner to the procedure followed in the present study, and observed a 50% reduction in the hypoxic response during isoflurane inhalation. We relate the absence of an inhibitory effect of isoflurane on the hypoxic response to additional behavioural drives that were introduced by active arousal of the subjects [17]. The introduction of additional drives such that the magnitude of the hypoxic responses between the control and isoflurane studies was not different was intentional. A reduction in hypoxic hyperpnoea by isoflurane could have resulted in a ventilatory stimulus insufficient to activate STP [3].

In the control study, ventilatory recovery from mild hypoxia ($P\mathrm{E}'_{\mathrm{O}_2}$ 6.2 kPa) showed an initial rapid decrease followed by a slow decay (ΔT ~ 56 s). In contrast, recovery from mild hypoxia during inhalation of 0.1 MAC of isoflurane showed a rapid decrease in $\dot{V}\mathrm{E}$ to just below baseline (ΔT ~ 18 s). A similar recovery pattern was observed at termination of a deeper level of hypoxia ($P\mathrm{E}'_{\mathrm{O}_2}$ 5.8 kPa) during isoflurane inhalation (ΔT ~ 15 s) (see also fig. 2). To characterize the dynamics of the ventilatory response out of hypoxia, we analysed the average responses using a simple model with two exponentials and common time delay [8, 15]. In the control study, two decaying components could be identified with time constants of 6.9 s and 126.0 s. In the isoflurane studies only one decaying component was identified with time constants of 4.2 s and 4.0 s for the Iso-1 and Iso-2 studies, respectively.

The factors that determine ventilatory recovery from brief episodes of isocapnic hypoxia are: the arterial $P\mathrm{O_2}$ waveform at the site of the peripheral chemoreceptors; the dynamics of the peripheral chemoreceptors; and activation of STP of breathing. An effect of isoflurane on one or more of these factors may be responsible for the reduction in ΔT.

At termination of hypoxia, the time at which the peripheral chemoreceptors detect normoxia depends on the $P\mathrm{E'_{O_2}}$ waveform (table 1), the (small) end-tidal to arterial $P\mathrm{O_2}$ gradient and the 5–6-s transport time from the lungs to the carotid bodies [22–24]. The loss of the hypoxic drive further depends on the fast dynamics of the peripheral chemoreceptors (time to peak discharge of the carotid sinus nerve after a sudden change in arterial $P\mathrm{O_2}$ is 1–5 s [25, 26]). We estimated that return to pre-hypoxic levels of the afferent input from the carotid bodies to the respiratory centres in the brain stem occurred between $t \sim 15$ s (time of the last hypoxic breath plus transport delay time) and $t \sim 18$ s (time of the first non-hypoxic breath plus transport delay time) of normoxia in the control study. We assumed that isoflurane, at the concentrations we have used, did not influence any of the above-mentioned factors and estimated the loss of hypoxic drive in the Iso-1 and Iso-2 studies between $t \sim 15$ and ~ 18 s and between $t \sim 12$ and ~ 15 s of normoxia, respectively.

The slow decay present during normoxic recovery from hypoxia in the control study is the manifestation of STP of breathing. Its time constant was larger than those observed in previous studies [8, 15]. The main difference between these studies is the higher $P\mathrm{E'_{CO_2}}$ background in the present study. Data from Fregosi in awake humans suggest that more intense stimuli (for example hypoxia plus exercise or hypoxia plus hypercapnia) result in longer periods of potentiation compared with less intense stimuli (hypoxia at rest, hypoxia plus normocapnia) [3].

In the Iso-1 study the absence of the slow decay of $\dot{V}\mathrm{E}$ during recovery from hypoxic hyperpnoea caused the reduction in ΔT (fig. 2). Furthermore, despite the more intense hypoxic stimulus, and the tendency for the ventilatory response to increase, a slow decay did not appear in the recovery pattern of the Iso-2 study. The time for $\dot{V}\mathrm{E}$ to return to baseline in the isoflurane studies was equal to the loss of hypoxic drive. These findings indicate that in both isoflurane studies, arterial $P\mathrm{O_2}$ and the dynamics of the peripheral chemoreceptors determined ventilatory decay and that central neuronal dynamics were not activated. As the ventilatory responses did not differ between treatments, the inability to activate STP was not related to the intensity of the hypoxic stimulus or to the magnitude of response, but to an effect of isoflurane. This is probably a specific effect on those respiratory neurones within the pontomedullary brain stem responsible for STP activation. However, an indirect effect of isoflurane, for example via an altered CNS arousal state, cannot be excluded (see below). Isoflurane and halothane [15] behave identically with respect to STP inactivation. It is noteworthy that in animal studies, STP of breathing is activated by various stimuli despite anaesthesia [1, 5]. It is possible that apart from the species difference this may be because of differences in stimulus intensities and techniques to activate STP.

In the control study we observed that the slow decay in $\dot{V}\mathrm{E}$ was predominantly because of potentiation of $V\mathrm{T}$ with no contribution from inspiratory and expiratory times (fig. 3). Similar observations have been made by Georgopoulos and colleagues [9]. During isoflurane inhalation, potentiation of $V\mathrm{T}$ was abolished. Furthermore, an increase in both $T\mathrm{E}$ and $T\mathrm{I}$ caused the decrease in $\dot{V}\mathrm{E}$ to less than baseline $\dot{V}\mathrm{E}$ (fig. 3). These changes waned slowly: at times > 120 s, $T\mathrm{I}$ and $T\mathrm{E}$ did not differ from baseline. It is not clear if the prolongation of the inspiratory and expiratory times and inactivation of STP (i.e. no potentiation of $V\mathrm{T}$) occurred at distinct anatomical sites within the CNS. For now we consider these phenomena together: they cause rapid changes in $\dot{V}\mathrm{E}$ and immediate hypoventilation at cessation of isocapnic hypoxic hyperpnoea.

We were unable to maintain strict control of $P\mathrm{E'_{CO_2}}$ in the VHV studies. This was partly because of the relatively low inspiratory gas flow that was insufficient for the minute volumes of the subjects during VHV. As a consequence, a mixture of air, expired gas via the expiratory limb and fresh gas via the inspiratory limb of the breathing system was inhaled with an inspired carbon dioxide concentration lower than the target concentration. The gain and time constant of the computer driven $P\mathrm{E'_{CO_2}}$ control were intentionally not altered to avoid $P\mathrm{E'_{CO_2}}$ oscillations and high inspired carbon dioxide concentrations. As $P\mathrm{E'_{CO_2}}$ waveforms were similar in the control and isoflurane studies, we consider comparison of the $\dot{V}\mathrm{E}$ recovery patterns from VHV between the two studies a valid procedure to demonstrate a possible effect of isoflurane on STP.

Despite the decrease in $P\mathrm{E'_{CO_2}}$ during VHV, $\dot{V}\mathrm{E}$ remained greater than baseline during the first 36 s of recovery in the control study (table 3, fig. 4B). This is attributed to activation of STP of breathing. Our data are consistent with the observation of others [10–14]. We relate the elevated $\dot{V}\mathrm{E}$ at > 45 s to the increase in $P\mathrm{E'_{CO_2}}$ during the first 90 s of recovery from VHV. In the isoflurane study, recovery from VHV displayed immediate hypoventilation during the first 24 s of normoxia. The absence of STP activation because of the central effects of isoflurane now yielded a ventilatory pattern dominantly controlled by the chemical stimuli to the chemoreceptors (i.e. hypoventilation because of hypocapnia). In healthy volunteers Wilkins, Reed and Aitkenhead noticed hypoventilation and arterial desaturation after 2 min of poikilocapnic VHV during inhalation of 50% nitrous oxide in oxygen but not while inhaling 50% nitrogen in oxygen [27]. Northwood and co-workers tested the effects of 75% nitrous oxide in oxygen on the recovery pattern from poikilocapnic ($P\text{E}'_{CO_2} \sim 3$ kPa) VHV in six normal subjects [12]. They observed apnoea and arterial desaturation in all subjects when told to relax after VHV (duration of apnoea 80 s; lowest saturation 75 %). We relate these observations to inactivation of STP of breathing by nitrous oxide, a property it shares with isoflurane. The results of our VHV studies are in agreement with those of our hypoxic studies. This indicates that slow central neuronal dynamics activated via a peripheral chemoreflex pathway and via a suprapontine pathway are equally sensitive to the effects of low-dose isoflurane.

We were unable to exclude explicitly the fact that the subjects cycled between arousal states ("sleep"–wakefulness) during recovery from hyperpnoea. It is therefore possible that our observations were influenced by an altered CNS arousal state. Fink and colleagues described the observation of post-hyperventilation apnoea in a subject who fell asleep at the end of VHV and resumed breathing on waking [28]. As alteration of the CNS arousal state is an inherent property of isoflurane, we feel that a distinction between the action on the ponto-medullary brain stem of the agent itself or its indirect action via an alterated arousal state is somewhat artificial. Furthermore, we do not believe that such a distinction would make our conclusions less valid.

STP exerts a stabilizing influence on $\dot{V}\text{E}$ [29]. For example, the absence of STP is observed in patients with congestive heart failure and nocturnal Cheyne–Stokes breathing [30]. In a previous study we showed that termination of 20 min of isocapnic hypoxia by normoxia results in a rapid decrease in $\dot{V}\text{E}$ to pre-hypoxic baseline. However, the identical procedure performed during inhalation of subanaesthetic halothane resulted in an undershoot 30% below normoxic baseline and in some subjects in the occurrence of central apnoea and arterial haemoglobin desaturation to < 80% [31]. We relate these ventilatory instabilities to inactivation of STP (see also [8]). Bearing in mind the fact that our studies have been performed in healthy volunteers, the findings from our current study and those of others [12, 15, 27] that inhalation anaesthetics, directly or indirectly, cause inability to activate STP may have important clinical implications. After surgery, inhalation anaesthetics persist for several hours in the body [32] and STP inactivation may, in part, be related to the frequent occurrence of hypoxic episodes after operation [15]. Furthermore, anaesthetics are often used for sedation or analgesia in a variety of clinical procedures. Hyperventilation and hypocapnia (for example because of pain or fear) may be followed by hypoventilation and arterial desaturation on administration of anaesthetics [12]. We suggest therefore that the arterial oxygenation of patients who breathe spontaneously and are or were exposed to inhalation anaesthetics should be monitored continuously using pulse oximetry.

Comparison of the pharmacodynamics and pharmacokinetics of an infusion of *cis*-atracurium (51W89) or atracurium in critically ill patients undergoing mechanical ventilation in an intensive therapy unit

A. H. BOYD, N. B. EASTWOOD, C. J. R. PARKER AND J. M. HUNTER

Summary

We have studied 12 critically ill, sedated patients who required a neuromuscular blocking drug to assist mechanical ventilation in an intensive care unit. Patients were randomized to receive an infusion of *cis*-atracurium 0.18 mg kg^{-1} h^{-1} (group 1, $n = 6$) or atracurium 0.6 mg kg^{-1} h^{-1} (group 2, $n = 6$) preceded, if necessary, by a bolus dose of $2 \times ED_{95}$ of the same drug (*cis*-atracurium 0.1 mg kg^{-1} or atracurium 0.5 mg kg^{-1}). Neuromuscular block was monitored using an accelerograph and the infusion rate adjusted regularly so that it was possible to detect the first response to train-of-four (TOF) stimulation of the ulnar nerve at the wrist. Blood samples were obtained for estimation of plasma *cis*-atracurium and laudanosine concentrations (group 1) or the three groups of atracurium isomers and laudanosine (group 2). There was no apparent haemodynamic or allergic response to either drug. The mean infusion time in group 1 was 37.6 h and in group 2, 27.5 h. On termination of the infusion, the time for the TOF ratio to reach 0.7 was similar in the two groups (group 1 = 60 min; group 2 = 62 min). The mean infusion rate of *cis*-atracurium was 0.19 mg kg^{-1} h^{-1} and of atracurium 0.47 mg kg^{-1} h^{-1} (expressed as mg of bis-cation): *cis*-atracurium was 2.5 times more potent than atracurium. Using the NONMEM program, a single compartment pharmacokinetic model was fitted to the plasma concentrations of *cis*-atracurium and the *cis-cis, cis-trans* and *trans-trans* isomers of atracurium. The mean population pharmacokinetic values for *cis*-atracurium were: volume of distribution (V) = 21 900 (SEM 416) ml; clearance (Cl) = 549 (79) ml min^{-1}; half-life ($T_{\frac{1}{2}}$) = 27.6 (3.6) min; and for the three groups of atracurium isomers were: *cis-cis*, $V = 15100$ (720) ml, $Cl = 449$ (42) ml min^{-1}, $T_{\frac{1}{2}} = 23.4$ (1.2) min; *cis-trans*, $V = 18000$ (667) ml, $Cl = 1070$ (43) ml min^{-1}, $T_{\frac{1}{2}} = 11.7$ (0.1); *trans-trans*, $V = 13100$ (1280) ml, $Cl = 1560$ (55) ml min^{-1}, $T_{\frac{1}{2}} = 5.8$ (0.4) min. Plasma laudanosine concentrations were lower in the *cis*-atracurium (peak value 1.3 μg ml^{-1}) than in the atracurium (maximum 4.4 μg ml^{-1}) group. (*Br. J. Anaesth.* 1996; **76**: 382–388)

Key words

Neuromuscular block, atracurium. Neuromuscular block, 51W89. Pharmacokinetics, atracurium. Pharmacodynamics. Intensive care. Pharmacokinetics, stereoisomers.

In the management of critically ill patients requiring mechanical ventilation in an intensive care unit, it may occasionally be necessary to administer a neuromuscular blocking drug together with sedative and analgesic agents. Indications for the use of neuromuscular blocking agents in such circumstances include: poor lung compliance, as in patients with adult respiratory distress syndrome; inability to synchronize the patient's own respiratory pattern with intermittent positive pressure ventilation (IPPV); raised intracranial pressure; status epilepticus; and to facilitate radiological imaging or inter-hospital patient transfer [1].

Atracurium, given by constant infusion, has proved useful in the management of the critically ill. It breaks down spontaneously in plasma (Hofmann elimination) and undergoes ester hydrolysis [2]. Thus its clearance is partially independent of renal and hepatic function, making it suitable for use in patients with multiple organ failure (MOF) [3]. Laudanosine, a metabolite of Hofmann degradation, is excreted partly by the kidney [4] and also by the liver [5]. Electroencephalographic changes in cats have been reported at plasma concentrations of > 4.4 μg ml^{-1} and convulsions in rats and dogs at a concentration of 17 μg ml^{-1} [6–8]. In pharmacokinetic studies of critically ill patients receiving atracurium by constant infusion without neuromuscular monitoring, plasma concentrations of laudanosine of up to 5 μg ml^{-1} have been detected [9, 10]. Although this concentration is higher than after a single bolus dose of atracurium 0.5–0.6 mg kg^{-1}, when plasma laudanosine concentrations peak at approximately 0.2–0.3 μg ml^{-1} [11, 12] there is as yet no evidence to suggest that laudanosine concentrations reported in patients with MOF are epileptogenic.

Atracurium is a mixture of 10 geometric isomers

A. H. BOYD, MB, CHB, FRCA, N. B. EASTWOOD, BSC, MB, BS, FRCA, C. J. R. PARKER, MA, MD, FRCA, J. M. HUNTER, MB, CHB, PHD, FRCA, University Department of Anaesthesia, Royal Liverpool University Hospital, Prescot Street, Liverpool L69 3BX. Accepted for publication: October 17, 1995.

each with different pharmacological characteristics [13]. There are three groups of these isomers: *cis-cis*, *cis-trans* and *trans-trans* atracurium. The 1R *cis*-1′R *cis* isomer, designated 51W89 and given the generic name, *cis*-atracurium, has been shown in humans to be approximately three times more potent than atracurium [14], to release less histamine [15] and, in animals, to have a higher affinity for the postsynaptic nicotinic receptor [16]. As a smaller mass of drug is required to produce the same degree of neuromuscular block, it would be expected that degradation of *cis*-atracurium might produce lower plasma laudanosine concentrations than those detected after atracurium.

This study was therefore designed to compare *cis*-atracurium with atracurium, given by constant infusion, in critically ill patients requiring neuromuscular block to facilitate mechanical ventilation. The aim was to assess dose requirements and any possible side effects of *cis*-atracurium. Plasma concentrations of *cis*-atracurium and the three groups of isomers of atracurium were measured and an attempt was made to compare the pharmacokinetics of *cis*-atracurium with the individual isomer groups of atracurium. The plasma laudanosine concentrations produced by the two drugs were also compared.

Patients and methods

The study was approved by the Hospital Ethics Committee. A clinical trial exemption certificate for the use of *cis*-atracurium was issued by the Committee on Safety of Medicines. Informed consent was obtained from the next of kin of all patients. Twelve patients, aged > 18 yr, were investigated consecutively, after a predetermined randomized sequence; six were allocated to receive *cis*-atracurium (group 1) and six to receive atracurium (group 2). Patients were considered suitable for entry into this study only when their medical management required the use of a neuromuscular blocking agent. Exclusion criteria included: pregnancy; known sensitivity to atracurium; personal or family history of malignant hyperthermia; clinically significant neuromuscular disease; major thermal injury; recent administration of a neuromuscular blocking agent for more than 24 h in the presence of renal failure; failure to demonstrate partial recovery of the train-of-four count after a previously administered neuromuscular blocking agent; prior administration of atracurium of more than 3 mg kg^{-1} within the previous 8 h; or administration of an atracurium infusion within the previous 4 days.

All patients admitted to the intensive therapy unit (ITU) were treated as indicated clinically, with sedative and analgesic agents given in accordance with the sedation policy of the ITU. If the patient had already received a neuromuscular blocking agent and did not have any of the exclusion criteria listed above, evidence of recovery from neuromuscular block was sought, using an accelerograph, before inclusion in the study. Thus a previously administered neuromuscular blocking agent might have been detectable in the plasma on entry into the study.

The physical characteristics, medical history and diagnosis of each patient were recorded (table 1), and also all medications administered in the 12-h period before and during administration of the neuromuscular blocking agent (table 2). A physical examination was performed and baseline recordings of vital signs such as arterial pressure, heart rate and temperature. Blood samples were obtained for estimation of haemoglobin, MCV, platelet count, white cell count, and serum concentrations of sodium, potassium, bicarbonate, creatinine, total bilirubin, alkaline phosphatase (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST), albumin and glucose. Illness severity scores (Apache II) [17] were recorded for the 24-h period immediately after commencement of the study. Urine was analysed for protein and blood.

Neuromuscular monitoring was quantified using an accelerograph (TOF-Guard, Biometer, Denmark). The skin over the ulnar nerve at the wrist was cleansed and gently abraided. Paediatric electrocardiographic electrodes were then applied to allow stimulation of the ulnar nerve at the wrist, using the train-of-four (TOF) twitch technique. The transducer was attached to the thumb to measure acceleration in response to contraction of the adductor pollicis muscle. The accelerograph records both the TOF count (T1, T2, T3, T4) and the TOF ratio (T4:T1), expressed as a percentage. Baseline measurements were determined before administration of the neuromuscular blocking agent.

Depending on the clinical situation, a bolus of the neuromuscular blocking agent followed by a constant infusion of the same drug was commenced or, if the patient had already received such a drug, the infusion was started without a bolus dose.

Those patients receiving *cis*-atracurium (group 1) were given a bolus dose of $2 \times ED_{95}$ (0.1 mg kg^{-1}), over 5–10 s, followed immediately by an initial infusion of 0.18 mg kg^{-1} h^{-1}; alternatively, a constant infusion was started at the same rate. Patients receiving atracurium (group 2) were given a bolus of $2 \times ED_{95}$ (0.5 mg kg^{-1}) or an initial infusion of 0.6 mg kg^{-1} h^{-1}, or both. The infusion of *cis*-atracurium or atracurium was subsequently adjusted to maintain the TOF count at 1 response only (T1). As few adjustments as possible to the infusion rates were made, and any changes were small. A record of the TOF count was noted whenever the infusion rate was changed, and at least once every 8 h if no alteration in the infusion rate had occurred during that period. The TOF count was also documented just before discontinuing the infusion and every 5 min thereafter until the TOF ratio was > 0.7.

A blood sample (5 ml) was obtained from each patient before administration of the drug. Further samples were obtained 15 min and 1 h after the initial bolus dose of either *cis*-atracurium or atracurium, or after commencement of the infusion (if a bolus dose had not been given). Blood samples were then obtained 15 min and 1 h after any alteration in the infusion rate and approximately every 8 h, if there had been no alteration in the infusion rate. Samples were also collected immediately before termination of the drug, at 2, 5, 10 and 20 min after

termination, and at 1, 3, 6, 12, 24, 36, 48, 72 and 96 h, wherever possible,

Each blood sample was placed immediately into a lithium heparin tube containing 0.02 ml of sulphuric acid 1.5 mol litre^{-1} and centrifuged. The plasma (2 ml) was decanted and acidified with 8 ml of sulphuric acid 15 mmol litre^{-1}. The acidified plasma was kept on ice and deep frozen within 30 min for subsequent analysis by solid phase extraction and high pressure liquid chromatography (HPLC) with fluorescence detection. The assay was validated using quality control samples derived from pooled human plasma. The lower limit of quantification (LOQ) was 10 ng ml^{-1} for all analytes. In group 1, the upper LOQ for *cis*-atracurium was 2140 ng ml^{-1} and for laudanosine 1410 ng ml^{-1}. In group 2 the upper LOQ values for *cis-cis*, *cis-trans* and *trans-trans* isomers of atracurium were 2800, 1580 and 250 ng ml^{-1}; the upper LOQ for laudanosine was 2000 ng ml^{-1}. The coefficient of variation for all analytes was $< 11.3\%$, except for the *trans-trans* atracurium isomers, which was 20.8%.

The non-linear mixed effects model program (NONMEM) [18] was used to fit a one-compartment model to the plasma concentrations of *cis*-atracurium from patients in group 1, and to the plasma concentration profiles of each of the atracurium isomer groups in those patients who received atracurium (group 2). The program fits a model to the data for all individuals collectively; rather than attempting to identify the pharmacokinetic variables of each individual separately, a population mean is determined. In principle, the inter-individual random variability in pharmacokinetic variables is also determined, but these results are not presented in view of the small sample size.

The models were described in terms of compartment volume and clearance. Elimination half-life was determined in additional NONMEM runs with the model described in terms of V and $T_{\frac{1}{2}}$. Attempts to fit a two-compartment model were unsatisfactory, presumably as a consequence of the sparsity of data points in the periods just after starting and finishing the infusion. In one patient who received atracurium (patient No. 7), the final three plasma concentrations were obtained soon after extensive debridement of soft tissue under general anaesthesia and within a few hours of death. Their inclusion in the data set used to fit the model was associated with large residual errors and difficulty in obtaining convergence of the routine to minimize the objective function. They were therefore omitted from the data set used to fit the model.

Results

The physical characteristics and diagnoses of the patients are shown in table 1. Patient No. 6 had received atracurium 135 mg and vecuronium 74 mg in the 24 h before admission into the study: he had

surgery for orthopaedic procedures and had also been transferred to another hospital for intracranial surgery during that time. Patient No. 9 had received vecuronium 10 mg, 2.5 h previously. Urea and electrolyte concentrations and liver function tests in each patient on entering the study are shown in table 2.

Medication administered to each patient concurrent with the infusion of neuromuscular blocking drug is given in table 3. All patients completed the study except for patient No. 7 who died while an infusion of atracurium was in progress. Brain stem death, after a severe head injury, was diagnosed in patient No. 6, 19.5 h after discontinuation of the infusion.

Of the six patients who received *cis*-atracurium, five were given an initial bolus dose together with an infusion. Patient No. 6, who had received atracurium and vecuronium before inclusion in the study, still had evidence of residual neuromuscular block when entered into the study (TOF count = 1). He received no initial bolus dose. The mean infusion rate for each patient, number of changes of the infusion rate, duration of each infusion and total dose given are shown in table 4. The TOF count on discontinuing the infusion and the time for the TOF ratio to reach greater than 0.7 are also given. The mean infusion rate for patients given *cis*-atracurium was 0.19 (range 0.16–0.21) mg kg^{-1} h^{-1} and the mean time for the TOF ratio to reach 0.7 was 60 (20–85) min.

Five patients were given a bolus of atracurium followed immediately by an infusion. Atracurium was initiated by infusion to patient No. 9, who had previously been given vecuronium, but she required an additional bolus 15 min later. The mean infusion rate for atracurium in group 2 was 0.47 (range 0.3–0.74) mg kg^{-1} h^{-1}. The mean duration of infusion for the atracurium group was shorter than that for the *cis*-atracurium group (27.53 *vs* 37.62 h). In patient No. 10 it was not possible to measure the time to a TOF ratio > 0.7 because of a fault with the accelerograph. The mean time to achieve a TOF ratio greater than 0.7 was 62 (41–82) min in the four other patients.

Analysis of the two batches of *cis*-atracurium used in the study showed one batch to contain 105.8 % of the stated amount (5 mg ml^{-1}) and the other to contain 110.1 %. Analysis of the atracurium used in the study indicated that it contained 109.2 % of the stated amount (10 mg ml^{-1}) and the following isomer composition: *cis-cis* 58.7 %, *cis-trans* 35.9 %, *trans-trans* 5.4 %. Pharmacokinetic variables, derived using the NONMEM program for *cis*-atracurium and each of the three groups of isomers of atracurium, are given in table 5.

The plasma concentrations of laudanosine in each of the patients during the infusion are shown in figure 1, and after discontinuing the infusion in figure 2.

As patient No. 7 died while still receiving an infusion of atracurium, there are only 11 plots in figure 2. Peak laudanosine concentrations obtained and values for area under curve of laudanosine against time are given in table 6. The peak plasma laudanosine concentration in patients given *cis*-

atracurium was 1.3 $\mu g\ ml^{-1}$, whereas in patients who received atracurium it was 4.4 $\mu g\ ml^{-1}$.

No haemodynamic disturbances or allergic reactions were associated with either the bolus dose or infusion of both neuromuscular blocking agents.

Discussion

In this study, the mean infusion rates of *cis*-atracurium and atracurium required for six critically ill patients were 0.19 and 0.47 $mg\ kg^{-1}\ h^{-1}$, respectively. The mean infusion rate of *cis*-atracurium was comparable with that reported by Stone, Pollard and Harper (0.17 $mg\ kg^{-1}\ h^{-1}$) in 12 intensive care patients [19]. The atracurium infusion rates were also similar to those reported in other studies in the critically ill [10, 20]. In this study, *cis*-atracurium was therefore approximately 2.5 times more potent than atracurium (with the dose of both drugs expressed as milligrams of the bis-cation). The dose of atracurium in the commercial preparation is expressed as milligrams of the salt: for our patients,

12	4.40	166.3

this is equivalent in clinical use to atracurium 0.63 mg kg^{-1} h^{-1}.

An infusion of *cis*-atracurium provided adequate neuromuscular block in our patients. As with previous clinical studies of this new drug [15], no obvious adverse cardiovascular or allergic effects were noted. None was noted in the atracurium group. Allergic responses to drugs are, in fact, uncommon in critically ill patients [21]. On discontinuing the infusion, the mean time for the TOF ratio to recover to greater than 0.7 was very similar after *cis*-atracurium or atracurium (60 *vs* 62 min). The TOF count on stopping the infusion, measured using the accelerograph, varied between 0 and 4 in patients given *cis*-atracurium, but was 0 in all patients given atracurium. However, we noted that it was possible, on occasion, to see the first response to the TOF without it being detected by the accelerograph. We do not therefore believe that there were significant differences in the degree of neuromuscular block on discontinuing the infusion between the patients studied; the accelerograph is not always accurate for use in this group of patients. It was chosen because it is compact, easy to use and does not require immobilization of the patient's arm for long periods of time. The time to achieve a TOF ratio > 0.7 of 60 min after either drug compares very favourably with vecuronium, after which the time to achieve a similar degree of recovery may taken more than 35 h in patients with MOF [22]. It is interesting to note that in the vecuronium study, the possibility of metronidazole inhibiting metabolism of the drug was raised [22]. Five of the patients in this study were receiving metronidazole (table 3), but there was no evidence of such an effect. It would seem that rapid recovery can be achieved after *cis*-atracurium has been given for many hours to critically ill patients, in the same way as has been reported after the use of atracurium [3, 20].

There was no evidence for the development of tolerance to the action of each of the neuromuscular agents in the two groups. In the *cis*-atracurium group, only patient No. 1 required a slightly greater infusion rate at the end of the study than at the beginning. In the atracurium group, a similar pattern was found: only patient No. 7 had increased requirements at the end of the infusion period. Although the maximum duration of infusion was only 47.6 h in group 1 and 34.2 h in group 2, Stone, Pollard and Harper also found no evidence for increasing requirements of *cis*-atracurium with time, even after infusions of up to 135 h duration. Evidence for the development of tolerance to neuromuscular blocking agents in the critically ill is mainly anecdotal [9] although it has been demonstrated in paediatric practice and in anaesthetized dogs [23, 24].

In the pharmacokinetic analysis of plasma concentrations of *cis*-atracurium (group 1) and the three groups of atracurium isomers (group 2), it was only possible to fit a one-compartment pharmacokinetic model to the data because of the relative sparsity of data points for individual patients at the times when the infusion was changed. Clearance of *cis*-atracurium was found to be 549 ml min^{-1}, with an elimination half-life of 28 min. These values were similar to those found in a study of healthy patients and patients with chronic renal failure given a bolus dose of *cis*-atracurium 0.1 mg kg^{-1} [25]. It was reassuring to find that the clearance of *cis*-atracurium was unchanged, and possibly increased, in these six critically ill patients. Once again there is evidence of spontaneous atracurium (or its isomer) breakdown irrespective of the residing body compartment [10, 12].

It is interesting to compare the pharmacokinetics of *cis*-atracurium with those of the three *cis-cis* isomers of atracurium (group 2), where clearance was 449 ml min^{-1} and $T_{\frac{1}{2}}$ 23 min. These differences probably reflect the presence of the two other *cis-cis* isomers in atracurium. There were other differences in the derived pharmacokinetic variables for the three groups of atracurium isomers. Clearance of the *cis-trans* isomer was approximately twice that of the *cis-cis* isomer, and that of the *trans-trans* group over three times that of the *cis-cis* isomer. The values for clearance and elimination half-life of the *cis-cis* and *cis-trans* isomers in this study were comparable with those of Tsui, Graham and Torda in a study of eight ASA I and II patients who were given a single bolus dose of atracurium 0.3 or 0.5 mg kg^{-1} [26]. These workers did not determine the kinetics of the very short-acting *trans-trans* isomer. Our study is the first to examine the pharmacokinetics of the three groups of isomers of atracurium in the critically ill patient.

Plasma laudanosine concentrations were smaller after *cis*-atracurium than after atracurium. The highest measured plasma concentration of laudanosine in group 1 was 1.3 µg ml^{-1}, and in group 2 4.4 µg ml^{-1}. Laudanosine concentrations after atracurium were comparable with those reported previously in the critically ill [9, 10]. No attempt was made to fit a pharmacokinetic model to the plasma laudanosine concentrations for several reasons. After administration of *cis*-atracurium or atracurium, laudanosine is produced continually as a metabolite at various sites. Thus the total dose of laudanosine given is unknown and the time course of laudanosine production cannot be determined. The AUC was calculated, however, to give an indication of the overall formation of laudanosine; it tended to be less in the group who received *cis*-atracurium than atracurium.

Acknowledgement

We thank the Wellcome Foundation plc for providing a grant towards this study and the *cis*-atracurium and atracurium.

Effect of isoflurane and sevoflurane on the magnitude and time course of neuromuscular block produced by vecuronium, pancuronium and atracurium†

L. E. H. VANLINTHOUT, L. H. D. J. BOOIJ, J. VAN EGMOND AND E. N. ROBERTSON

Summary

We have compared the ability of equipotent concentrations of isoflurane and sevoflurane to enhance the effect of non-depolarizing neuromuscular blocking drugs. Ninety ASA I and II patients of both sexes, aged 18–50 yr, were stratified into three blocker groups (Vec, Pan and Atr), to undergo neuromuscular block with vecuronium ($n = 30$), pancuronium ($n = 30$) or atracurium ($n = 30$), respectively. Within each group, patients were allocated randomly to one of three anaesthetic subgroups to undergo maintenance of anaesthesia with: (1) alfentanil–nitrous oxide–oxygen ($n = 10$); (2) alfentanil–nitrous oxide–oxygen–isoflurane ($n = 10$); or (3) alfentanil–nitrous oxide–oxygen–sevoflurane ($n = 10$) anaesthesia. During maintenance of anaesthesia, end-tidal concentrations of isoflurane, sevoflurane and nitrous oxide were 0.95, 1.70 and 70%, respectively. Both the evoked integrated electromyogram and mechanomyogram of the adductor pollicis brevis muscle were measured simultaneously. In the Vec and Pan groups, a total dose of 40 $\mu g\ kg^{-1}$ of vecuronium or pancuronium, respectively, was given, and in the Atr group a total dose of atracurium 100 $\mu g\ kg^{-1}$. Each blocker was given in four equal doses and administered cumulatively. We showed that 0.95% isoflurane and 1.70% sevoflurane (corresponding to 0.8 MAC of each inhalation anaesthetic, omitting the MAC contribution of nitrous oxide) augmented and prolonged the neuromuscular block produced by vecuronium, pancuronium and atracurium to a similar degree. (*Br. J. Anaesth.* 1996; **76**: 389–395)

Key words

Anaesthetics volatile, isoflurane. Anaesthetics volatile, sevoflurane. Measurement techniques, electromyography. Measurement techniques, mechanomyography. Neuromuscular block, vecuronium. Neuromuscular block, pancuronium. Neuromuscular block, atracurium.

Various inhalation anaesthetics augment neuromuscular block produced by non-depolarizing neuromuscular blocking agents to a different degree. Although sevoflurane appears to increase both intensity and duration of neuromuscular block induced by vecuronium and pancuronium [1–4], the magnitude of this effect has not been quantified in a homogeneous population. Such information is clinically relevant; for example potentiation of blocker effect during administration of sevoflurane and reversal of this potentiation on withdrawal of this short-acting inhalation agent may reduce blocker dose requirements in the peroperative period and decrease the risk of residual curarization after operation.

Previous studies comparing the effects of isoflurane and sevoflurane on vecuronium block have produced inconclusive results. These studies were unable to show any significant difference for the effects of 1.15% isoflurane and 1.70% sevoflurane (both with 70% nitrous oxide [1, 2]) or for the effects of 1.15% isoflurane and 2.05% sevoflurane (both with 66% nitrous oxide [3]) on the block produced by vecuronium. Another interaction study, comparing opioid–nitrous oxide–oxygen and opioid–nitrous oxide–oxygen–sevoflurane anaesthesia, could not demonstrate any significant influence of sevoflurane with concentrations less than 2% on the duration of vecuronium-induced block [4].

In order to clarify the inconsistencies in the literature on the interactions between sevoflurane and neuromuscular blockers, we have compared the effect of equipotent concentrations of isoflurane and sevoflurane on non-depolarizing neuromuscular block in a carefully selected, homogeneous population of young adults. In this population the minimum alveolar concentrations (MAC) of isoflurane and sevoflurane in air–oxygen were found to be 1.15% [5] and 2.05% [6], respectively. The addition of 65–70% nitrous oxide reduces the MAC of both agents to 0.50% [5] and 1.10% [7], respectively.

Patients and methods

After obtaining approval from the Institutional Review Board and written informed consent, we studied 90 healthy adult patients, aged 18–50 yr, of both sexes, ASA I or II, undergoing elective surgical

procedures of an anticipated duration of $\geqslant$ 90 min under general anaesthesia. Patients were excluded if they had cardiac, pulmonary, renal, hepatic, neurological, psychiatric, muscular, inflammatory, malignant or endocrine diseases, as were pregnant women and patients with recent exposure (< 72 h) to medications known to interfere with neuromuscular transmission. Those more than 20 % overweight, according to life insurance tables [8], or those with clinical laboratory abnormalities (i.e. serum electrolyte, creatinine, BUN, SGOT, LDH, alkaline phosphatase or GGT concentrations) were also excluded.

Patients were stratified into one of three blocker groups (Vec, Pan, and Atr) consisting of 30 patients each. Within each blocker group, patients were allocated randomly to one of three anaesthetic subgroups, to undergo maintenance of anaesthesia with either: (1) alfentanil–nitrous oxide–oxygen (non-halogenated anaesthetics group (NHA)) (n = 10); (2) alfentanil–nitrous oxide–oxygen–isoflurane (isoflurane group (Iso)) (n = 10); or (3) alfentanil–nitrous oxide–oxygen–sevoflurane (sevoflurane group (Sev)) (n = 10).

After an overnight fast, patients were premedicated with diazepam 0.1 mg kg^{-1} orally, 60–90 min before induction of anaesthesia. Before this, patients were given Ringer's solution 1.5 ml kg^{-1} per hour of fasting. Alfentanil 100 μg kg^{-1} was administered as a bolus i.v. followed by a variable rate infusion of alfentanil 0.5–1.5 μg kg^{-1} min^{-1}. Three minutes after the alfentanil infusion was started, anaesthesia was induced with propofol 3.5–5 mg kg^{-1} i.v. in divided doses. The trachea was intubated without neuromuscular block. Anaesthesia was maintained with the anaesthetic technique selected during the randomization procedure. End-tidal concentrations of isoflurane, sevoflurane and nitrous oxide were targeted at 0.95 %, 1.70 % and 70 %, respectively. For the population studied, the MAC values of isoflurane and sevoflurane in air–oxygen were defined as 1.15 % [5] and 2.05 % [6], respectively. The contribution of nitrous oxide to the MAC value of the inhalation agent was calculated applying the concept of additivity of MAC fractions, where the individual MAC values of each gas (in this case nitrous oxide and sevoflurane or isoflurane) are summated to find the MAC value of the combination [9]. Equipotent concentrations of isoflurane and sevoflurane were defined as equal fractions of the MAC of either volatile anaesthetic without the MAC contribution of nitrous oxide [10].

After 40 min of stable end-tidal anaesthetic concentrations (within 5 % of the target values), an end-tidal carbon dioxide partial pressure of 4.7–5.3 kPa, stable haemodynamics with a systolic arterial pressure > 100 mm Hg and a stable baseline neuromuscular transmission recording, the blocker was administered i.v. in a cumulative manner, as described below. During the procedure both central and thenar skin temperatures were maintained between 35.5 and 36.5 °C using surface heating.

ECG monitoring of lead II was performed continuously and arterial pressure was measured intermittently by automated sphygmomanometry (Dinamap, Criticon, Tampa, USA). The arterial pressure cuff was placed on the arm opposite to the site where neuromuscular transmission was assessed. Thenar skin temperature was monitored using a thermocouple placed on the dorsum of the hand from which the response to ulnar nerve stimulation was recorded. Central temperature was measured using a rectal probe. The end-tidal concentrations of carbon dioxide, nitrous oxide, isoflurane and sevoflurane were measured continuously and displayed by a multiple gas analyser (Capnomac Ultima, Datex). This gas analyser was calibrated once every week using a calibrating gas (Quick Cal, Datex). Neuromuscular transmission was evaluated using both the evoked integrated electromyogram (IEMG) and the mechanomyogram (MMG) of the ipsilateral adductor pollicis muscle. The stimulating current, consisting of supramaximal rectangular pulses (duration 100 μs) into a train-of-four (TOF) pattern (frequency 2 Hz), was generated by the stimulating unit of the Datex Relaxograph and delivered every 20 s (0.05 Hz) to the ulnar nerve at the wrist via s.c. 27-gauge steel needle electrodes, placed 30 mm apart. The hand and forearm were immobilized in supination and abduction on a splint and the fingers were strapped in extension. The thenar electromyographic signal was detected using gelled silver–silver chloride skin electrodes. These were placed over the belly of the adductor pollicis muscle (the active recording electrode), at the distal phalanx of the second finger (the reference recording electrode) and midway between the stimulating and recording electrodes (grounding electrode). The force transducer was mounted so that the thumb was exposed to a preload of 200 *g*, measured continuously and recorded. During the study, a preload of 100–300 *g* was accepted.

For each blocker group, a cumulative dosing regimen was designed in which all patients undergoing maintenance of anaesthesia with different anaesthetic techniques were given the same amount of neuromuscular blocking agent. In the Vec and Pan groups, a total dose of 40 μg kg^{-1} of vecuronium or pancuronium, respectively, was given and in the Atr group a total dose of atracurium 100 μg kg^{-1} was given. Each blocker was injected in four equal doses and administered cumulatively. For vecuronium and pancuronium, an initial dose of 10 μg kg^{-1} and three increments of 10 μg kg^{-1} each were administered. For atracurium, an initial dose of 25 μg kg^{-1} and three increments of 25 μg kg^{-1} each were administered. Each dose of neuromuscular blocking agent was injected as an i.v. bolus over < 5 s into a rapidly running infusion.

As soon as the patient was anaesthetized, baseline evaluations of neuromuscular transmission were started and continued for 40 min before administration of the neuromuscular blocking agent. The mean of 10 first twitch (T1) responses, immediately preceding the first administration of neuromuscular blocking agent, became the control to which all subsequent T1 responses were compared. Each dose increment was given (at times $t1$, $t2$ and $t3$, respectively) only after the effect of the previous dose had reached a stable response, defined as three equal

Table 1 Patient characteristics (mean (pooled SEM or range)) in the different anaesthetic subgroups within the vecuronium, pancuronium and atracurium groups. NHA = No halogenated anaesthetic ($n = 10$), Iso = isoflurane ($n = 10$), Sev = sevoflurane ($n = 10$). % Ideal wt = body weight expressed as percentage of ideal weight for height. Within the three blocker groups, there were no significant differences between the subgroups NHA, Iso and Sev in age, weight and % ideal wt

(±1%) consecutive IEMG or MMG T1 responses, or when 7 min had passed with no decrease in T1 from control.

DATA ANALYSIS

Age, weight and percentage of ideal weight for height between the nine subgroups were compared using one-way analysis of variance (ANOVA). The Ryan–Einot–Gabriel–Wesch multiple range test (REGW test) [11] was applied subsequently to identify eventual sources of difference.

Within each blocker group, the time schedule in which the four doses of the neuromuscular blocking agents were administered was compared between the three anaesthetic subgroups, by comparing the times to injection of the first (*t*1), second (*t*2) and third (*t*3) increments after administration of the initial dose, using one-way ANOVA. The REGW test was applied subsequently to identify eventual sources of difference.

The individual dose–effect relationship was examined by plotting the logarithm of the dose against the logit transformation of T1 depression relative to control

$$\text{Logit(E)} = \alpha \times \log_e D - \beta$$

where $\text{Logit(E)} = \log_e(\text{E}/(\text{Emax} - \text{E}))$; E = T1 depression relative to control (%); Emax = maximal effect, that is 100%; D = dose, administered cumulatively; α = steepness coefficient; and β = intercept.

Because logit 0 and logit 1 do not exist, 0% and 100% T1 depression were considered as missing values. Lines of best fit were computed using linear least squares regression. The doses required for 50%, 90% and 95% T1 depression (ED_{50}, ED_{90} and ED_{95}, respectively) were calculated from the regression line.

The regression lines were tested to determine if they deviated from parallelism [12]. If they did not, ED_{50}, ED_{90} and ED_{95} values were compared between the subgroups. Parallelism was tested using one-way ANOVA and subsequent REGW test of the steepness coefficients of the regression lines (α). Comparison of the ED_{50}, ED_{90} and ED_{95} values between subgroups was performed using one-way ANOVA and subsequent REGW test.

Duration of action was defined as the interval between injection of the last neuromuscular blocking agent increment to 90% T1 recovery (T90) and to 70% T4/T1 recovery (TTOF70). T90 and TTOF70 were calculated on both the IEMG and MMG by linear intrapolation between the nearest neighbour measuring points [13].

In the current study, significant baseline drift with time was defined as failure of the IEMG T1 to recover to ≥ 90% of the pre-blocker T1 reference level, with T4/T1 > 0.90. In patients showing significant baseline drift with time, the IEMG-based T90 was considered as a missing value.

If, within the blocker groups, administration of the neuromuscular blocking agent was the same in each of the anaesthetic subgroups, T90 and TTOF70 values were compared between the anaesthetic subgroups by means of one-way ANOVA. The REGW test was applied subsequently to identify the source of difference.

Within the anaesthetic subgroups, IEMG-based ED_{50}, ED_{90}, ED_{95}, T90 and TTOF70 values were compared with the corresponding MMG-based variables using the two-tailed paired Student's *t* tests.

Statistical calculations were performed with the Statistical Applications Software of the SAS Institute (SAS/STAT Release 6.03, SAS Institute Inc, Cary, USA). All statistical tests were two-sided. $P < 0.05$ was considered to indicate statistical significance.

Results

We studied 108 patients, but the results from 18 were excluded because of measurement errors, technical failures or deviations from the study procedure. Within the blocker groups, there were no significant differences in age, weight, percentage of ideal weight for height or sex distribution between the anaesthetic subgroups (table 1).

The mean concentrations of isoflurane ($n = 30$) and sevoflurane ($n = 30$) were calculated to be 0.82 (SEM 0.01) MAC and 0.83 (0.01) MAC, omitting the MAC contribution of nitrous oxide, and 1.49 (0.02) MAC and 1.50 (0.01) MAC, respectively, including the MAC contribution of 70% nitrous oxide.

Within the blocker groups, the times of administration of the first (*t*1), second (*t*2) and third dose (*t*3) increments did not differ significantly between the anaesthetic subgroups (table 2).

Table 2 Times (mean (pooled SEM)) to cumulative dose administration after the initial dose: increments 1, 2 and 3 were injected at times T1, T2 and T3, respectively, in the different anaesthetic subgroups within the vecuronium, pancuronium and atracurium groups. NHA = No halogenated anaesthetic ($n = 10$), Iso = isoflurane ($n = 10$), Sev = sevoflurane ($n = 10$). Within the three blocker groups, there were no significant differences between the subgroups NHA, Iso and Sev for *t*1, *t*2 or *t*3

Group	Anaesthetic technique	*t*1 (min)	*t*2 (min)	*t*3 (min)
Vecuronium	NHA	5.8 (0.2)	9.8 (0.3)	12.9 (0.3)
($n = 30$)	Iso	6.1 (0.2)	10.0 (0.3)	13.2 (0.3)

For the blocker groups, the slopes of the cumulative dose–response curves did not differ significantly between the anaesthetic subgroups (table 3). The ED_{50}, ED_{90} and ED_{95} values, calculated for the subgroups Iso and Sev, were not significantly different. There was a significant difference in ED_{50}, ED_{90} and ED_{95} values ($P < 0.01$) between the subgroups receiving halogenated volatile anaesthetics (Iso and Sev) and the subgroup receiving opioid–nitrous oxide–oxygen anaesthesia (NHA) (table 4, fig. 1). There were no significant differences between the ED_{50}, ED_{90} and ED_{95} values determined using the IEMG or MMG.

In the blocker groups, T90 and TTOF70, measured for the subgroups Iso and Sev, were not significantly different. There was a significant difference in T90 and TTOF70 ($P < 0.01$) between the subgroups receiving the halogenated volatile anaesthetics and the subgroup receiving opioid–nitrous oxide–oxygen anaesthesia (table 5).

Fourteen patients exhibited significant IEMG baseline drift with time. Within the blocker groups, there were no significant differences between IEMG- and MMG-based T90 values for the patients exhibiting no significant baseline drift with time. Also, there were no significant differences between IEMG- and MMG-based TTOF70 values in all patients.

Discussion

We have demonstrated that equipotent concentrations of isoflurane and sevoflurane (i.e. 0.95 % and 1.70 %, respectively) augmented and prolonged vecuronium-, pancuronium- and atracurium-induced neuromuscular block to a similar degree compared with opioid–nitrous oxide anaesthesia. The concentrations of isoflurane and sevoflurane corresponded to 0.8 MAC, omitting the MAC contribution of nitrous oxide, and to 1.5 MAC, including the MAC contribution of 70 % nitrous oxide.

The current interaction study differed from previous ones [1–4] in that anaesthetic-related effects on neuromuscular blocking agents were compared within a carefully selected homogeneous population of young adults, using IEMG and MMG responses of the adductor pollicis brevis muscle simultaneously.

MAGNITUDE OF BLOCK

If administered in equipotent concentrations, inhalation anaesthetics enhanced vecuronium-, pancuronium- and atracurium-induced neuromuscular block to an approximately equal extent. The IEMG and MMG tend to detect similar magnitudes of block after administration of either vecuronium, pancuronium or atracurium. Similar observations have been made previously with tubocurarine [14]. The results of the current study are at variance with those of Engbæk and Roed [15] using pancuronium. Their findings may be explained by different conditions of anaesthesia, or recording electrode positioning [16] and stimulation frequency, or both [17].

The MMG-based potency estimates, assessed in the current study with an opioid–nitrous oxide–oxygen anaesthetic, were consistent with previously determined values for vecuronium [18, 19], pancuronium [20] and atracurium [18, 19] using the cumulative dose technique.

Our conclusions regarding the effect of isoflurane and sevoflurane on non-depolarizing neuromuscular block are in keeping with those of Morita and coworkers [3] who were unable to detect any significant difference between the potentiating effects of 1.15 % isoflurane and 2.05 % sevoflurane in 66 % nitrous oxide (i.e. 1 MAC of either vapour in oxygen–air without the MAC contribution of nitrous oxide) on neuromuscular block produced by vecuronium. However, the ED_{50}, ED_{90} and ED_{95} values calculated, using the single dose technique, were less than the current cumulative dose values. Redistribution between successive cumulative doses may explain the greater ED_{50}, ED_{90} and ED_{95} estimates in the current study. Moreover, the end-tidal concentrations of isoflurane and sevoflurane in their study (1.15 and 2.05 %, respectively) were approximately 20 %

higher than those used in the current study (0.95 and 1.70%, respectively). Additionally, there may be other factors (i.e. anthropometric, ethnic [21] or environmental [22]) that could have affected the sensitivity to vecuronium.

The cumulative dose technique, used in the current study, may underestimate the potency of the neuromuscular blocking agent with rapid distribution and elimination. However, administration of a neuromuscular blocking agent was consistent throughout the study and the volatile agent was chosen randomly; thus the degree of redistribution would have been similar in all patients within a blocker group undergoing maintenance of anaesthesia with different techniques. Additionally, the aim of the current study was to determine anaesthesia-related effects on non-depolarizing neuromuscular block and not to provide absolute potency estimates.

DURATION OF ACTION

In equipotent concentrations, both inhalation anaesthetics prolonged vecuronium-, pancuronium- and atracurium-induced neuromuscular block to a similar degree. The IEMG- and MMG-based TTOF70 values may be used interchangeably for the three neuromuscular blocking agent studied. Similar findings have been shown previously for atracurium [23] and tubocurarine [14]. However, during offset of neuromuscular block, IEMG T1 should be interpreted with caution as it may be unstable with time. The MMG-based T90 values assessed in the current study were comparable with previously published MMG T90 values during opioid–nitrous oxide–oxygen anaesthesia for vecuronium [24, 25], pancuronium [26] and atracurium [27] and during opioid–nitrous oxide–isoflurane anaesthesia for atracurium [27, 28].

Recent studies on the effect of sevoflurane on duration of vecuronium-induced neuromuscular block yielded data that showed wide variation on the extent of prolongation [2–4]. However, there were several methodological differences compared with our study. First, in these studies, patient ages ranged from 22 to 77 yr [2], 22 to 62 yr [3] and 25 to 75 yr [4], respectively. Second, offset of neuromuscular block was measured using the evoked IEMG, which was shown to be unreliable in 5–42% (18% in the current study) of patients [29]. As advancing age is associated with a greater incidence of slow recovery after vecuronium [5], and because the IEMG is unreliable during offset of non-depolarizing neuromuscular block [30], considerable between-patient variability in duration of neuromuscular block may have been produced within the populations studied. In the investigation of Saitoh, Toyooka and Amaha [2], the scatter in the duration of neuromuscular block, after the same dose of vecuronium ($0.2\ \mathrm{mg\ kg^{-1}}$) was so large that significant differences in the duration of neuromuscular block with opioid–nitrous oxide and opioid–nitrous oxide–isoflurane (end-tidal isoflurane concentration = 1.15%) anaesthesia could not be demonstrated. Therefore, comparison of such inaccurately determined recovery variables between these heterogeneous populations produces results that should be interpreted with caution.

Performance assessment of a fuzzy controller for atracurium-induced neuromuscular block†

D. G. MASON, N. D. EDWARDS, D. A. LINKENS AND C. S. REILLY

Summary

The performance of a fuzzy controller for atracurium-induced neuromuscular block was assessed. Ten ASA I or II patients undergoing surgery anticipated to last at least 120 min were studied. A Datex Relaxograph was used to monitor neuromuscular block. Initially the T1 set point was set at 10% of baseline for at least 30 min (phase I). The T1 set point was then increased to 20% and then returned to 10% for two further periods of at least 30 min duration (phases II and III). The mean (SD) of the mean T1 error in 10 patients for phases I, II and III were 1.1 (1.4)%, −0.43 (1.2)% and 0.28 (0.94)%, respectively. The results show that a simple fuzzy logic controller can provide good accuracy with insensitivity to set point changes despite the considerable inter-individual variation in infusion rate required. (*Br. J. Anaesth.* 1996; **76**: 396–400)

Key words

Computers, fuzzy logic. Neuromuscular block, atracurium.

The provision of neuromuscular block is a fundamental part of anaesthesia. It is important that the degree of neuromuscular block is sufficient to provide adequate surgical conditions, while not so excessive as to make it difficult to antagonize at the end of surgery.

The degree of neuromuscular block is usually monitored by observing the muscle response to nerve stimulation, commonly the ulnar nerve. Bolus doses of neuromuscular blocker are usually administered intermittently based on this response. However, this method inevitably leads to fluctuations in the degree of neuromuscular block, particularly with recently introduced short-acting agents. To reduce this effect, continuous infusions of neuromuscular blocker may be used, but differences in pharmacodynamics and pharmacokinetics between patients make it difficult to choose the correct infusion rate to maintain the desired level of neuromuscular block [1]. Closed-loop control offers the ability to provide a stable level of neuromuscular block allowing for variations in individual responses to neuromuscular blocking agents.

Fuzzy logic control is a simple, although effective, technique for controlling non-linear and uncertain processes [2, 3]. The effect of neuromuscular blockers is non-linear and fuzzy logic provides a simple way to create a non-linear controller. Fuzzy logic accommodates uncertainty by dealing in imprecise, qualitative terms such as low, medium and high. This also provides control rules which are easy to understand and therefore simple to modify.

The derivation of the fuzzy rules is a common bottleneck in the application of fuzzy logic controllers. Conventionally, these fuzzy rules are based on emulating the control actions of an expert. Such a case was reported recently with the clinical application of fuzzy logic control to arterial pressure regulation using isoflurane [4]. However, with neuromuscular block no such experience is readily available to draw on for derivation of the fuzzy rulebase. This situation was the main driving force behind the introduction of self-organizing fuzzy logic controllers [5]. For this study, however, a fuzzy rulebase was hand-crafted based on a simulation involving the non-linear atracurium dose–response characteristic comprising pharmacokinetics and pharmacodynamics [5].

A particular configuration of fuzzy logic controller known as PD+I (proportional, differential plus integral) was found to be appropriate for this application via the use of computer simulation studies [5]. This fuzzy controller comprises separate PD and I components which correspond to dynamic and memory parts, respectively. The error signal (E) between the actual and desired TI value is processed first to form the differential ($D = dE/dt$) and integral (I) components. The error signal (E) gives the proportional component (P) directly. These error signals which are input to the fuzzy controller first need to be scaled to suit the particular control application. The separate outputs of the fuzzy PD and fuzzy I components also require scaling to suit the specific application. These input and output scaling factors for this fuzzy controller were identified by iterative computer simulations until good control performance was observed. We then assessed the performance of this fuzzy atracurium controller in clinical practice.
